VAN NOSTRAND'S
ECLECTIC
ENGINEERING MAGAZINE.

No. I.—JANUARY, 1869.—Vol. I.

In introducing to the Profession this novelty in engineering literature, the Publisher would respectfully submit the following considerations:

First.—Although the matter is to be selected from the professional serials, it will not largely consist of articles, nor slices of articles, merely cut out of current literature, and reprinted.

The object is, not to present specimens, but abstracts of the current fact and opinion. These abstracts are intended to be the net result—the useful impression that would remain upon the mind of an expert, after carefully reading the mass of matter from which they are derived. The condensation must, therefore, be performed more by the pen than by the scissors.

Second.—The reason why such a magazine is introduced, is that the great body of Engineers and Artisans can rarely afford the money to buy, and never the time to digest the whole volume of professional literature. Excellent and indispensable as are the few serials so widely circulated, each in its own department, they do not largely embrace other departments, and they deal too much in specifications, and details of evidence and argument, to be thoroughly read; they are rather consulted for special information, and filed for reference.

It is therefore proposed that several experts, actively engaged in different branches of the profession, and hence competent for the task, shall specially devote a part of their time to searching out and compiling such information, that all others interested may keep themselves informed in these great arts and sciences, liberally and intelligently, but also easily, agreeably, and at a small expense of money and time.

Especial effort will be made to weed out of the matter compiled, all that is irrelevant, inconclusive, and merely formal; and also to present the cardinal points, rather than the minutiæ of evidence and specification.

There are, of course, occasional leaders, papers, reports, and abstracts which should not be omitted, but which can hardly be condensed without being garbled.

The French and German magazines will be largely translated, and professional news will be gathered from all sources.

The following pages are confidently referred to, in farther explanation.

THE SITUATION.

The past year has witnessed a large development in many new and a few remarkable enterprises, and it has presented to the profession more than the usual number of revolutionary schemes and "great expectations." The rapid advancement of the Pacific Railroad, and of lines of transportation all over the world; the enlargement of communication by telegraph between innumerable little towns as well as between continents; the extension, by engineering works, of commerce and civilization at large, and more noticeably in America since our energies have been concentrated upon the arts of peace, and notwithstanding the commercial dullness due to political uncertainties, the remarkable increase of manufacturing and preparations for manufacturing in all departments;—these enterprises have fully kept pace with the requirements and the spirit of the age. It is proposed in the present article merely to refer to the condition and to the direction of progress in a few of the engineering works and problems most prominent just now in America. In a future number of the Magazine the spirit of the *new year editorials*—those careful and often excellent reviews of work done and laid out, that give so much value to the January numbers of the professional serials—will be faithfully compiled.

Railways.—A radical improvement has been commenced in locomotive practice. Ten years ago it seemed probable that engines and freight trains especially would be lightened, to save the permanent way. Meanwhile the economy of long trains, despite the rapid destruction of permanent way by the necessarily heavy engines, was established, and then, as is usually the case when the right system has been ascertained, a way—a steel way—was provided to carry it out. But the radical improvement to which we refer, although in the same direction, affects the locomotive itself. To draw heavier trains, and at the same time to decrease road wear, would seem to demand two opposite qualifications in the same machine. We may indeed set heavier boilers and machinery upon 10 or 12 driving wheels, but such a length of rigid wheel base wastes in lateral strains and frictions, what it saves in the distribution of vertical load. The "missing link" in the system was the *lateral articulation* of the locomotive, and this has now been supplied in several forms, which will be hereafter referred to. Fairlie's plan, already introduced in England and in America, is placing upon 2 independent locomotives without boilers, a single boiler capable of driving both with only the attendance required by one. Freeborn's system, which has only reached the stage of working drawings and expert indorsement, is the communication of engine-power to any number of independent trucks by means of bevelled gearing. Gearing is not a favorite word in locomotive practice, but we think its standing is likely to be improved.

Carrying 6 or 8 tons on 1 wheel in a train requires as much strength of permanent way as if every wheel bore the same load. When driving wheels carry but 2 or 3 tons each, like other wheels (and the articulation of rolling stock makes this feasible), the permanent way may be reduced in strength and cost 2 or 3 fold, and will be so reduced with advantage on lines of light traffic; or the endurance of a given weight of permanent way may be indefinitely increased. To this end, indeed, the superstructure of heavily worked lines abroad is being strengthened, while at the same time the individual strains are being reduced. All this promises economy in the working and maintenance of way and power.

It should also appear that the maximum weights of cars are reached. There are sleeping coaches on the Erie road weighing 40 tons, with 9-ton trucks. The greatest profits are made, of course, on luxuries, and railway companies can hardly overdo the matter; but we think *railway* shareholders might have a little larger interest in such profits, and that the most Golden Alhambras might be put on more wheels, or cut up into smaller Boudoirs. There is, however, a growing tendency towards lighter parts; this is accomplished by better shapes, but chiefly by the substitution of steel for iron. In England, the use of iron tyres, crank pins, rods and axles, would be considered barbarous. And in this country steel rails and tyres are introduced with commendable rapidity, and the demand for steel shapes is increasing. When iron rails break by the 1,000 a month, as on the Erie, and tests are rarely if ever required by purchasers, the necessity for subjecting steel to the most rigid and often inappropriate trials seems rather sudden; but we hope the severity of tests will rather be increased than diminished —we only ask that they may bear some relation to actual service.

Other improvements are coming forward. We can but mention them at the present writing: The close coupling of cars by elastic buffers to prevent oscillation; the interposition of elastic media between parts subjected to jarring, as in frogs and wheels; the use of interchangeable parts in rolling stock; the lateral relief of rolling stock by means of the Bissell truck and its modifications, and better workmanship, chiefly due to better tools.

Railway accommodation in the matter of car comforts, such as atmospheric air to breathe, and water to hold and transfer heat, is making notable progress; but in the matter of station conveniences, there is room for improvement—room in many instances that had better be occupied before it gets too costly. If the older London stations—Paddington, Kings Cross, etc.—were not models of fitness, the defect has been corrected in the St. Pancras station 690 feet by 240 feet under a single roof. But in the western metropolis we have no railway stations—only places on the map at or about which passengers embark or alight. This is, perhaps, not to be regretted. Any costly down-town stations in New York would only postpone the grand work that is certain to be built—a roof 1,000 feet long and indefinitely wide, in Harlem, where passengers land from underhouse or overhouse railways leading to the Battery, and whence they depart directly for the east and north, and by way of a high bridge across the Hudson for the south and west. In Philadelphia a similar grand plan is more nearly worked out. All the lines entering that city will soon terminate under a new St. Pancras on the bank of the Schuylkill, opposite the waterworks. In the western cities the building of stations has been undertaken on a liberal scale, and in many cases carried out on a permanent and suitable plan.

The disestablishment of railways, placing them under Government management, is not likely to be undertaken here at present; but the thorough discussion of the subject in England will at least reform abuses in the present system.

Meanwhile highway transportation, which has been growing more expensive and unsatisfactory for 1,000 years or more, is likely to be improved. In the vicinity of cities, light steam passenger-cars are substituted for horse-cars. Mr. Bridges Adams advocates the laying of rails on all principal highways. Notwithstanding the better adaptation of the steam-carriage to indifferent roads by means of rubber tyres, some sort of rail or tram giving a smooth, hard bearing, will be found indispensable, whatever motive power may be used. The advantages of the rail are minimum width and cost of way, and convenience in steering; its disadvantages are flange friction and inconvenience in turning out. The plank road is too perishable to be considered, except as a temporary expedient. The great American mud road is utterly bad, unnecessary, and disgraceful. In short, what we have to do is to pave the way for cheap steam power. Cheaper and quicker common road transportation is one of the most important and most neglected problems of the day; railway managers little realize what they are losing by ignoring it. Thousands of isolated villages that go to seed under the "accommodation" of a Concord coach at 4 miles an hour, would grow into large centres of traffic and revenue if connected with the nearest railway by a tram-road, upon which a 4-ton locomotive could run at 8 miles an hour. But until very lately the idea of an intermediate stage between a 100-ton train on a regulation railroad, and a lumber wagon in the mud, seems not to have been largely considered.

Iron and Steel.—It would be difficult to exaggerate the collateral advantages of the Bessemer process. Were that great art to be lost to-day, the impetus it has given to cognate arts—to invention and discovery in the treatment and means of treating iron at every stage, from the mine to the ultimate market, would have already rendered it the most important invention of modern times. We cannot undertake in this article even to mention all the promising enterprises in this direction. The Bessemer process in Europe is producing not less than half a million tons of steel per year. In America it is now fully established. After making some bad steel, and some that was unsuitable for the purposes intended, in the course of long experiments with untried irons, the mills at Troy and Harrisburg are now regularly turning out rails and shapes that are as regularly accepted after rigid tests and comparisons with the foreign steels. The Freedom and the Cleveland works have also commenced successful manufacture. Suitable ores for Bessemer steel are plentiful in all parts of the United States. But the blast furnace practice, with some exceptions, is irregular and uncertain.

One of the collateral advantages of the Bessemer process abroad, has been the creation of such a demand for pure, highly carburized, uniform pig iron, that any expense was warranted in order to meet it. And the sooner the furnace managers in this country grapple with this problem, with a determination to solve it, the better it will be for all concerned. Speaking of blast furnace practice, the hot blast, always considered economical, but not always productive of the best iron, is now deemed equally valuable for both quality and quantity. The hot blast brings down more impurities, but *suitable fluxes* eliminate these impurities. The utilization of furnace gases was at one time abandoned in certain districts, but more skilful working has removed the difficulties encountered. Indeed, in the best American practice, the detention of the gases at the tunnel head, by means of mechanical feeding apparatus, has been found unnecessary; the gases are utilized before they arrive at the tunnel head. It should certainly seem absurd to throw into the air a great volume of flame, and then complain that there is no flame-giving gas to be spared. Increased height of furnaces—over 100 feet in the Cleveland district—has largely increased the yield, and bettered the quality of pig-iron. The increased contact of the iron with incandescent carbon from this cause, is of peculiar advantage for the production of Bessemer metal. It is true that the increased temperature due to a high stack and the hot blast reduces and combines every metal of which the ore exists in the material charged—manganese, aluminium, silicum, etc.—but the greater number of the metals so reduced are valuable alloys, and the remainder may be eliminated by proper fluxing. But the capacity of the English coke to sustain the weight of the charges in a 100 feet furnace is an advantage that cannot be certainly predicted for our anthracite. It is to be hoped that the proper shaping of the boshes, and other mechanical and working features, will give us an equal advantage—or rather, it is to be hoped that our blast furnace managers will test, at some little cost, the capacities of home materials with reference to modern foreign practice. We are not doubtful as to the result, if we can only get a thorough test.

Several new processes for decarburizing crude iron are on trial. In America the mixture of magnetic ores with fluid cast-iron, and in England the pouring of crude iron upon a carbon-bearing mineral—nitrate of soda—are at least practicable substitutes for the finery process. Whether they are more than this remains to be proved, and the hopes of a wider range of interests than those directly concerned are hanging upon the results.

The development of flame furnaces, for heating and puddling, is one of the leading improvements. The Siemens furnace almost rivals the Bessemer process in practical economy. The production and burning of coal gas has been achieved by various inventors, in various ways, but the regenerative feature of the Siemens furnace enables it to maintain an intensity and a regulated quality of flame, that should preserve the material treated and the furnace itself against excessive waste. Under the Pomeroy patents, the use of manganese as a purifier, and of steam both as a heating and a purifying agent in the furnace, excellent steel is being produced from old iron rails and Franklinite ore or residuum. The Chenot steel process, depending upon the securing and utilization of the wrought-iron sponge first formed in the blast furnace, and other modes of treatment at every stage of manufacture, are having the benefit of thorough trial. The Siemens-Marten process, the production of steel of various grades from crude wrought-iron and cast-iron, in the Siemens furnace, is well established abroad, and has been successfully commenced, under favorable auspices, here.

Meanwhile the old crucible steel process, or rather the new crucible steel process, instead of being superseded by the other processes, has had the benefit of such improvements and economies, that it is still the close competitor of them all. It is fortunate for us that the best English talent and experience has found a residence among us.

For the production of steel castings, the Bessemer process is thus far inadequate—the metal cannot remain "dead melted" long enough to part with its bubble-giving gases. But the crucible process is to-day producing steel castings —gearing, frogs, cranks, and substitutes for wrought-iron forgings, that are excellent substitutes for forgings, in every particular. This manufacture is so new among us that we hardly appreciate its importance.

In the machinery for working iron and steel, we have more metal and better fitting. The steel rail train at Harrisburg and the new iron trains at Reading are as ponderous and accurate as marine engine work. We have but few heavy steam hammers in this country, and no hydraulic forging presses. The use of wrought-iron box-frames for hammers, cranes, etc., has hardly commenced here, although it is common abroad.

Steam Navigation has experienced no radical change of late. The size of ships is creeping up to Great Eastern proportions. The greater the size, the less the working cost for a given speed; always provided the vessel is loaded to her full capacity. The Great Eastern is simply premature. A most important change in the structure of iron hulls is hardly recognized by the leading builders, strange to tell, although long since brought forward. This is the longitudinal system—running the ribs lengthwise instead of vertically, so as to add their enormous strength in the direction of the principal strain. No amount of strength in the present vertical frames of a ship will prevent her breaking in two. In marine engines and boilers there is little change, although there has been much costly experimenting. Excessive superheating, surface condensation, high-pressure, and the use of liquid fuel, are slow and difficult problems. Wood bearings have overcome the chief obstacle in the working of heavy screw machinery, and the screw steamer is driving the paddle steamer from the sea. With the screw the power of the wind can be added to that of steam, but paddles work at a disadvantage in a vessel rolling and careening under a spread of canvass,

Iron Structures, bridges, houses, etc., are multiplying among us. On the principal railways, such as the Pennsylvania, the wooden bridge is the exception. If the old wooden trusses and trestles so common on the older American roads, are not soon pulled down, there will be some frightful "accidents." We regret to observe that so many costly buildings are going up in our cities with wooden floors. We think it could be proved that iron would pay in the long run, at twice its present cost. A little economy of external and as a rule inappropriate ornamentation, would pay for fire-proof and durable floors.

New Sources of Power.—Captain Ericsson's startling proposition to utilize the direct heat of the sun, has been published, and, in fact, practised on an experimental scale during the past year. The foreign authorities do not receive the announcement hopefully and with proper respect, but they are accustomed to sudden conversions, as in the matter of the monitors. The application of tides and wind to mechanical uses has hardly been advanced. Here are three forms of power—infinite, universal, and free—going to waste century after century, while we are delving in the depths and under the sea for costly coal to convert into power. We cannot believe that the limit of human ingenuity is reached—rather that these subtle forces are held in reserve for the uses of a wider and grander civilization.

THE NEW YORK SOCIETY OF PRACTICAL ENGINEERING.

This Society, organized a few months since, holds regular fortnightly meetings at room 24 Cooper Institute building, for the discussion of engineering subjects of a practical nature and of public interest. Meetings were held on the evenings of November 24 and December 8 respectively, the President (James A. Whitney) in the chair.

At the meeting of the 24th ult., the regular paper on "Elevators and Hoisting Machinery" was read by Mr. T. P.

Pemberton. The writer passed from a brief consideration of the most primitive methods of raising weights by means of a rope thrown over the branch of a tree to the construction of the rude capstans and windlasses that, until within the past hundred years, were used on the vessels and in the mining operations of most nations, and are still found on Chinese junks. From this he passed to a classification and description of the several classes of elevators now employed in mines, buildings, manufactories, etc. The use of traversing cranes for large workshops was strongly advocated, and sketches given of those employed in England, and capable of lifting and carrying a large locomotive from one end of the shop to the other. The use of ropes, either of hemp or wire, in elevators for carrying persons was discountenanced, and elevators worked by screws were recommended for all such cases. In the discussion which followed, a method was explained by which it is believed large, masses of rock were lifted in ancient times, and which consists in tilting the rock alternately upon each of two fulcrums placed at a slight distance apart under the centre of the mass, each fulcrum being slightly raised as the rock was tilted up therefrom. An elevating apparatus which is used in Great Britain, and to some extent in American mines, was described as consisting of two vertical series of platforms, having an alternate reciprocating movement in opposite directions, so that by stepping to and from the platforms of one series to those of the other, the miners, by the upward movement of the platforms, may be carried from the bottom to the top of the shaft.

At the meeting of the 8th inst., the regular paper on "Modern Improvements in Mining Apparatus" was read by Mr. Wm. B. Harrison, and sketched the development of machinery in mining operations from the primitive wash-pan to the modern improvements in stamp-mills, amalgamators, and the like. An interesting discussion sprang up after the reading of the paper, in which Dr. A. W. Hall sketched his experience in the mining districts of the Rocky Mountains, and the economy which has resulted in the amalgamating process, by placing the mercury as a coating upon copper. A Mr. Ferris, from California, gave a detailed description of the method of hydraulic mining in that State. Dr. J. N. C. Smith, ex-Mayor of Boston, gave a graphic description of what had fallen under his observation in travels in Asia, stating his belief that unknown mines still exist in that ancient country, and giving also a sketch of a rude turbine wheel which he had seen in one of the valleys of Anti-Lebanon, and which had been in use there for ages before American turbines were thought of. After some further discussion on ancient and modern appliances relating to the matter in hand, the Society adjourned for two weeks, with the announcement that at the next meeting the regular subject for consideration would be "The Prevention of Marine Disasters."

ENGINEERING PROBLEMS.

The Council of the Institution of Civil Engineers invite communications on the subjects comprised in the following list, as well as upon others; such as, 1st. Authentic Details of the Progress of any work in Civil Engineering, as far as absolutely executed (Smeaton's Account of the Eddystone Lighthouse may be taken as an example); 2d. Descriptions of Engines and Machines of various kinds; or, 3d. Practical Essays on Subjects connected with Engineering, as, for instance, Metallurgy. For approved original communications the council will be prepared to award the premiums arising out of special funds devoted for the purpose.

1. On the present state of knowledge as to the strength of materials.

2. On steam cranes, and on the application of steam power in the execution of public works.

3. On the theory and details of construction of metal and timber arches.

4. On land-slips, with the best means of preventing or arresting them, with examples.

5. On the principles to be observed in laying out lines of railway through mountainous countries, with examples of their application in the Alps, the Pyrenees, the Indian Ghâts, the Rocky Mountains of America, and similar cases.

6. On railway ferries, or the transmission of railway trains entire across rivers, estuaries, etc.

7. On the systems of fixed signals at present in use on railways.

8. Description of a modern English locomotive engine, designed with a view to cheapness of construction, durability, and facility of repair.

9. On the leading points of difference between the engines and carriages in use on railways in the United States and in Great Britain, and the reasons for any peculiarities in the American practice, with details of the cost of maintenance.

10. On the most suitable materials for, and the best mode of formation of, the surfaces of the streets of large towns.

11. On the construction of catch-water reservoirs in mountain districts for the supply of towns, for irrigation, or for manufacturing purposes.

12. Accounts of existing water-works, including the source of supply, a description of the different modes of collecting and filtering, the distribution throughout the streets of towns, and the general practical results.

13. On pumping machinery for raising water, both for high and low lifts.

14. On the drainage of towns and the ultimate disposal of town refuse.

15. On the employment of steam power in agriculture.

16. On the ventilation and warming of public buildings.

17. On the design and construction of gas-works, with a view to the manufacture of gas of high illuminating power; and on the most economical system of distribution of gas, and the best modes of illuminations in streets and buildings.

18. Critical observations on estuary tides.

19. On the construction of tidal or other dams, in a constant or variable depth of water; and on the use of wrought iron in their construction.

20. On the arrangement and construction of floating landing stages, for passenger and other traffic, with existing examples.

21. On the different systems of swing, lifting, and other opening bridges, with existing examples.

22. On the measure of resistance to bodies passing through water at high velocities.

23. On the results of the best modern practice in ocean steam navigation, having regard particularly to economy of working expenses, by superheating, surface condensing, great expansion, high pressure, etc.; and on the "life" and cost of maintenance of merchant steamships.

24. On ships of war, with regard to their armor, ordnance, mode of propulsion, and machinery.

25. On the measures to be adopted for protecting iron ships from corrosion.

26. On coal mining in deep workings, including machinery for dispensing with gunpowder in "getting" coal.

27. On the present systems of smelting iron ores, of the conversion of cast-iron into the malleable state, and of the manufacture of iron generally, comprising the distribution and arrangement of iron-works.

28. On machinery for rolling heavy rails, shafts, and bars of large sectional area, and for forging heavy masses of metal.

29. On steel, and its present position as regards production and application.

30. On the safe working strength of iron and steel, including the results of experiments on the elastic limit of long bars of iron, and on the rate of decay by rusting, etc., and under prolonged strains.

31. On machinery for washing lead ores.

32. On the present state of submarine telegraphy, and on the transmission of electrical signals through submarine cables.

THE GREATEST AMERICAN RAILWAY.—The Pennsylvania Railroad has at last effected the actual consolidation with it of its two main Western connecting routes. The Pittsburgh, Fort Wayne, and Chicago, and the Pittsburgh, Cincinnati, and St. Louis Roads thus become practically a part of the Pennsylvania Central, and over 1,000 miles of railway, stretching from the seaboard to the great cities of the Mississippi Valley, pass under the control of a single corporation. The nature of this gigantic combination, effected by the great Pennsylvania line while ours are busy feeing lawyers and procuring injunctions, may be better comprehended in the light of the fact that it brings under one management property valued at $280,000,000, and reaches for freight and passengers from Philadelphia to Chicago, Cincinnati, and St. Louis.—*N. Y. Tribune.*

EXCAVATING IN QUICKSAND.

SHEET PILING; PUDDLE WALLS; OBSTRUCTING WATER.

Condensed from a paper by Wm. J. McAlpine, C. E., before the American Society of Civil Engineers.

Description of Works.—In the autumn of 1866 an earthen dam was built across a small valley near the head of the Acushnet river, to form the storing reservoir of the New Bedford Waterworks. The dam was 600 feet long, 25 feet high, 20 feet wide on top, with slopes on each side of 2 to 1. The earth about the dam is the decomposed primary rocks, similar to that of the general coast range, being coarse and fine gravel and sand, with a little vegetable loam on the surface, and with no clay or almost none. Below the surface muck was a stratum of hard pan of irregular thickness from one to three feet, and beneath this was a bed of fine sand, which by subsidence and pressure was so hard as often to require to be picked before it could be removed with the shovel.

The earthen dam was exceedingly well built. There was a puddle wall of ample width in the middle, which was extended in all cases to the hard pan, and generally 4 to 6 feet below it, with a "toothed" bottom. The muck under the upper slope of the dam was removed to the hard pan, and in some cases the muck was also removed from beneath the lower slope. The puddle wall was made of the best materials that could be procured in the neighborhood, which was fine gravel, mixed with coarse and fine sand, and the loamy sand from the surface, all of which were incorporated together by the free use of a large quantity of water and by cutting with spades. The upper slope of the dam was protected by a well-made slope wall of very large-sized quarry stone. The reservoir or lake when full, covered about 200 acres, and the water was 20 feet deep at the dam. The gate house was built at the western end of the dam at the foot of the upper slope of the bank, and the waste culvert and conduit were extended from it entirely through the earthen dam. The foundations of the gate house and culvert were placed at the level of the lowest water in the river, which was about 3 feet lower than the surface of the swamp and were made by placing on the hard compact sand, a floor of large unhewn blocks of granite, with the edges and end joints hammered off to lines. The stones were laid on a bed of hydraulic cement mortar, and great care was taken to fill the vertical joints tight. The waste culvert was in the form of a segment of a circle of 8 feet chord, and 3 feet versed sine. The conduit was an oval of 3 and 4 feet diameters, made by 3 courses of brick. Its grade was 5 feet higher than that of the culvert, and it was supported on top of the latter from the gate house to near the middle of the bank, and then was curved to the right and was supported through the lower half of the embankment on a puddle wall. All this work was laid in excellent hydraulic mortar.

The lake was filled with water during the early summer of 1867, and remained full until February, 1868. The dam and the waste culvert were frequently examined during this period of 6 months. The dam itself was perfectly tight. A very small stream of water escaped at the lower end of the waste culvert, but this ran clear, and evidently came from the hill side. The workmen drank it, because of its purity and low temperature. The water in the lake at that time was highly colored, and at a comparatively high temperature. There were a few very small holes in the bottom stone and in the arch, where very cold clear water escaped almost in drops. The author first visited the work in June, 1867. The lake had not then been filled, but the water in the river had been shut back so as to be at a level 5 or 6 feet higher than the bottom of the gate well. A leak had occurred through its foundation (the stone pavement), which had brought up with the water considerable fine sand. A new floor was then being laid on the inside of the well, which completely stopped the leak at that place.

The Breach and its Causes.—About the middle of February, 1868, there occurred an exceedingly heavy fall of rain, and as there had been two months of previous heavy rains, and the ground was then frozen, the engineer apprehended that the water might rise too high in the lake. He therefore raised one of the gates at the gate house, giving an opening of 6 square feet under 20 feet head. Three days later he sent an intelligent man to close this gate. This person asserts positively that he shut the gate, but he adds that the water continued to flow out through the waste culvert in undiminished quantity, and it is therefore certain either that the rod attached to the gate was broken from it, and thus the gate was not closed, or that the leak in the gate well of the previous June had made a passage under the gate house, and had forced upward some of the pavement stones of the waste culvert.

Several intelligent persons were at the dam within 1 day of the time that the breach occurred, and did not observe anything wrong. No one witnessed the breach, which occurred 48 hours after the gate was supposed to have been closed, and swept out 100 feet in length of the embankment, and discharged probably within a few hours 300,000,000 of gallons of water. Fortunately the dense cedar forest which extended for half a mile below the dam, so much obstructed the flow of this large body of water as to prevent much damage on the river below. The rush of water at the dam undermined the waste culvert and lowered the pavement 2 or 3 feet, and also toppled over the gate chamber. The author visited the work the middle of May to determine upon the plans for the repairs of the dam and works. It was very important to discover, if possible, the causes which had produced the breach, but a sufficient number of facts had not been ascertained to determine these causes definitely, and it therefore became necessary to review all of those which *might* have produced the accident:

1. The stone pavement had been placed on a bed of quicksand, which although very hard and compact when dry and undisturbed, became a semi-fluid when saturated and subjected to disturbance. It was well bedded in hydraulic cement mortar, and the joints filled as close as possible, but it was practically impossible to make these joints all perfectly tight, and many of the openings between the stones, in places, were of considerable width. The discharge water passing through the culvert had a velocity of 10 feet per second, which was sufficient to force its way downward into any imperfect joint, and to rapidly wear away any portion of imperfect mortar until it reached the very fine sand on which the pavement rested; and this would be quickly removed by such a current of water, and cause 1 or more of the stones to settle, and then the current would rapidly extend its efforts under other stones, and soon cause the culvert to settle and break and leave the lake water free egress through the embankment. That the pavement had some such imperfect joints was shown by the leak which had occurred in June previously, and that the pavement was undermined as above hypothetically stated, by finding the stones at a level 2 or 3 feet lower than that at which they were originally laid.

2. The segmental form of the waste culvert arch produced a horizontal thrust upon the stones forming the foundation. These stones did not extend entirely across the foundation (transversely). That is, from 3 to 4 stones were used to make up the width of 12 feet. This thrust was produced by the weight of the stone arch and of a body of earth, which, in moist condition, would bring a weight of 40 tons per lineal foot on the arch, and to resist it was only the inertia of half a ton, the friction on the earth, and the resistance to the compression of moist or wet earth of less than 2 square feet area. These single stones may, therefore, have been forced into the earth horizontally, and thus joints opened to the attack of the current of water, or the arch stone may have slid upon the pavement, and in either case allowed the arch to fall and thus open a passage for the lake water through the embankment.

3. The conduit having an unequal support in passing through the embankment, may have become cracked at or near the place where it lost the support of the culvert masonry, thus admitting water into the embankment (which in this place had been made of fine sand), thus carrying it off.

4. The water from the lake under 20 feet head might have forced a small passage through the fine sand entirely below the base of the dam and of the foundation of the masonry, and gradually enlarging itself have finally produced the breach.

A consideration of all of the circumstances of the case led to the belief that the breach was caused by the first of the conditions above named, and that it was probably aided by the second. Nevertheless, it was regarded as prudent to provide in the new work as far as possible, against *all* of the causes which might have produced the disaster. The plans which were determined for the repairs were as follows:

Plans for Repairs.—1. To remove the quicksand across the breach, for the whole width of the base of the dam, as low as could be done without great expense, and replace it with fine gravel, mixed with a little loam (which was the best material which could be procured without hauling a dozen miles).

2. To place the waste culvert at a level 3 feet higher than in the original structure, so as to have its foundation resting on the greatest possible depth of gravel, and to build the culvert and conduit as 1 piece of masonry entirely through the bank.

3. To place the gate house about 40 feet above the upper toe of the dam, and extend a bank of gravel to cover the culvert and conduit from contact with the water in the lake.

4. To *place* within the main bank 2 rows of water-tight sheet-piling, which should extend as deep as possible into the quicksand below, and at least 20 feet horizontally into the old bank to the east of the breach, and at least as far into the side hill at the west, and to make a gravel puddle wall between these rows of piling, sunk as deep and as far into the banks at the ends as practicable.

5. To remove the slope wall from the face of the old bank and from the hill side for at least 60 feet horizontally, and face the bank anew with gravel of 3 feet thickness at top and 6 feet at bottom (at right angles to the slope).

To foot this facing at least 4 feet deep into the swamp, and in all cases to the stratum of hard pan, to which it should be carefully connected, and to uncover this stratum of hard pan for a circuit of 100 feet radius above the toe of the dam, examine its depth and make it (by adding gravel) a perfect lining over the whole bottom, and at its upper extremity to connect it with a cut-off of gravel sunk 4 feet deep into the underlying stratum of quicksand.

These precautions may at first thought seem to have been further extended than the case warranted, but a personal examination would soon convince an experienced engineer that it was really one of the worst cases that he is often required to meet. The disturbance in the bed of quicksand had changed it from a material of hard consistence to a semi-fluid, which flowed in from all directions and left the whole of the earth about the work porous or perhaps cavernous.

Sheet Piling.—Engineers often use sheet-piling by driving single planks or timbers, sometimes with tongues inserted and sometimes with a double course breaking or covering the joints. The author holds the opinion that in most cases such sheet-piling is not only useless, but is positively detrimental, and for a great many years he has used none but *placed* sheet-piling; that is, by excavating a trench to the requisite (or greatest practicable) depth, and placing in the bottom a timber, to which closely jointed plank are spiked (being also spiked to a similar timber at the top), and covered by a second course of jointed boards or plank. In other words, making a barrier perfectly water-tight against the head of water which will be brought against it. When the plank are thus placed, the trench is filled with fine gravel mixed with a little loam. It is impossible to drive plank singly and make a water-tight joint. The tongues or coverings are generally useless.

To prove this, let the greatest care be taken in driving some plank in a dry place. Then remove the earth and you will find the bottom joints of the piling open in both directions; and if tongues have been used, many of them will be found to have been split off at the bottom, and useless, and no covering plank can be put on, much less driven, which will make the joints water-tight. Such sheet-piling will not resist one foot head of water; and if water will pass through, then will the fine sand and loam or clay, and the whole piling becomes not only useless but deceiving to the engineer who has relied upon it; and who may from that cause lose his structure.

Angles to Obstruct Water.—But this is not all of the danger to be apprehended. Water will follow along a smooth surface for a great distance (horizontally and vertically), until it finds these open joints, through which it will freely pass, and then upon the opposite side, where it will continue to search for some escape under or around the structure. Water abhors angles, and by compelling it to make a sufficient number, its head can be entirely destroyed and prevent any damage. The interposition of these angles is often the weapon of defence that the engineer can avail of, against his worst enemy, and most useful ally—water. In placed sheet-piling you can provide at the bottom as many of these right angles as you deem necessary by means of the plank and timbers, which will generally give you seven angles, and these may be increased to any desired number.

Clay *vs.* Gravel Puddle.—Many young engineers fill their piling trenches with clay puddle. The author greatly prefers fine gravel, with a little loam mixed with it. The first coffer dam at the United States dry dock gave way, chiefly because it was filled with clay. The one built by the author withstood a great pressure because it was filled with gravel. Even paving stones were allowed to be put in the coffer dam, where they were surrounded by gravel. The particles of clay are cohesive, and a vein of water never so small, which finds a passage under or through clay, is continually wearing a larger opening. The particles of fine gravel, on the other hand, have no cohesion. Such a vein of water as has been mentioned, first washes out from the gravel the fine particles of sand, and the larger particles fall into the space, and these small stones first intercept the coarser sand and next the particles of loam, which are drifted in by the current of water, and thus the whole mass puddles itself better than the engineer could do with his own hands. The vacuities produced below, by this operation, are indicated by the settlement at the top, where more gravel, etc., can be added as is found necessary.

An embankment of gravel is comparatively safe, and becomes tighter every day. One of clay is much tighter at first, but is always liable to breakage, from the causes already mentioned. For the same reasons the piling trench should be filled with gravel, so that if any vein of water escapes through or below the sheet-piling, the weight of the gravel will crush down and fill up the vein, before it can enlarge itself enough to produce danger.

Difficulties to be Overcome.—The problem now before us was one of considerable difficulty. The sounding rods showed that the material to a depth of from 20 to 25 feet, was of the same character as that at and above the level of the river, viz.: a very fine sand, in fact a very troublesome quicksand. It was necessary to excavate a piling-trench in this semi-fluid to a depth of at least 15 feet. On the one side we had the river flowing through a wooden sluice and canals, and a heavy embankment of 25 feet height pressing down upon the bed of quicksand adjacent to the pit. On the other side was a steep side hill of 50 feet height pressing down upon a similar bed of quicksand. The excessive rains had filled the swamp and lands adjacent to the pit with water, to their utmost point of saturation. This quicksand was very pervious to water, and hence a large quantity of water might be anticipated to come into the pit during the operation, and if the work was protracted, the high banks on each side would be undermined and cave into the pit.

A steam engine of nominally 10-horse power and a pump, delivering 40 cubic feet of water per minute 13 feet high, were provided, but the power applied was $5\frac{1}{2}$ times the effect produced, which covered the friction of the machinery, increased greatly by the sand, and the loss of the water by loose buckets. The power of the engine was exhausted by the time the depth of 12 feet was reached.

Rules for Removing Quicksand.—There are 3 rules to be observed in excavating quicksand, and they are here stated concisely so as to impress the reader:

1. The water must be removed promptly and thoroughly.

2. The excavation must be made with the utmost despatch.

3. The material must not be disturbed after it begins to quake.

Now, these rules are almost never observed. It is almost impossible to make either engineers, foremen, or workmen follow them, and hence arise the chief difficulties and expense of removing quicksand. If they are strictly followed, the author guarantees that the difficulties and expense will be reduced one-half at least. Quicksand is defined to be a mixture of fine sand, with such a proportion of clay or loam as enables the mass to retain water within itself; and when in this condition, after it has been trampled upon for a short time, it begins to quake, so that it may also be called "quakesand." When it reaches this condition, if it is left quiescent for a few hours, the heavier particles of sand and clay settle down and expel the water, and the mass becomes again firm. If, on the other hand, it is further disturbed by the feet of the workmen, it becomes more and more fluid, additional material flows in from the sides, and no progress can be made in the excavation.

When the engineer has such a work in hand he should provide an ample pumping power. And here it may be noted that in most cases he will find that a power even 5 times as great as he anticipated will often in the end prove most economical. The pumps should be capable of lifting sand as well as water, and those are best which are not liable to be clogged. This is of more consequence than that they should work with a good "duty."

The author has found that in most cases sheet-piling protections around the pit to prevent the influx of sand are useless and often detrimental. If there is room to allow the excavation to take its natural slope, and the 3 rules are observed, the sheet-piling protection will be found unnecessary. Quicksand in a dry state may be excavated nearly vertical. These views will be illustrated by describing the operations at the place in question.

The Operations of Repairs.—The pit was commenced on top about 50 feet wide and 100 feet long. There were 30 laborers employed, who were arranged as follows: Six were kept constantly employed in removing and casting aside the sand from about and under the pump, to keep it far below the other parts of the excavation; 12 men were constantly employed in opening small ditches radiating out from the pump pit; 6 men were employed in excavating the ridges left between the radiating ditches, and as long as the latter were kept open these ridges offered perfectly dry digging. The remainder of the men were employed in casting further back the earth which was thrown out by the 6 men last mentioned. It will be seen that the actual removal of the earth was measured by that done by only 6 men out of 30, but these men had perfectly dry work.

All things being in readiness, the work of excavating was commenced early in the morning, and by mid-day the pit had been sunk in the lowest place to a depth of 12 feet, and then it appeared that the extreme power of the steam engine to remove the water had been reached, and it soon became impossible to keep open the radiating ditches, and consequently the earth between them became suffused, and soon after the whole of the lower portion was transformed from hard compact sand to a mass of semi-fluid material, quaking like jelly. The water began to "boil up" in many places in the bottom, and it was evident that no further progress in the excavation could at this time be made.

It was considered very important that the sheet-piling should be placed at a much greater depth than that to which the excavation had now been carried. To *drive* the plank to the desired depth, as has already been mentioned, would have resulted in open joints at the bottom. It was therefore determined to lessen the *number* of such joints by making up the plank in panels of 4 feet width, with joints matched and battened with 1-inch boards. One of these panels was placed in the proper line of the sheet-piling, and forced down by *pressure* nearly 5 feet deep. The non-fluid condition of the sand permitting this penetration, a second panel was forced down in the same manner, and with considerable trouble a tolerably close joint was made with the first panel, and further secured by a plank which was driven over the joint.

In this manner successive panels were driven in, until the whole width of the pit was covered by 2 rows of sheet-piling placed 15 feet apart. As the joints between the panels thus placed were of necessity nearly as open as in any other sheet-piling, it was determined to remove the water, and then the earth from *between* the rows of piling to the depth to which they had been forced, and then to batten and caulk up the joints on the inside.

Source of Water Determined by Temperature.—While the question of a new engine was being discussed, it became desirable to ascertain how much of the water which flowed into the pit, came from the leaky sluice and the canals, and how much from the natural water courses through the sand. The material being of so porous a character, it was impossible to determine this question merely from the directions in which these small streams came, but the author happening to have his pocket thermometer with him, he obtained the *temperature* of the water flowing into the pit from various quarters. The result was surprising. The temperature of the water in the sluice was 74°, and that of one set of the streams ranged from 71° to 73°, and of another set was from 56° to 61°, several of them flowing but a few feet from each other, with these widely differing temperatures.

Those of the higher degrees were evidently the leakages from the sluice-way and canal, and those of the lower temperature as evidently from deep-seated springs.

A rough, but sufficiently accurate gauge of each of the 20 small streams was made, from which it was ascertained that two-thirds of the water which came into the pit was leakage, the greater part of which could be prevented by a new sluice, and a better connection at the ends. With a diminution of more than one-half the quantity of inflowing water, the engine on hand would be of ample power to free the work from water, and enable us to get down to the requisite depth, and caulk the joints of the sheet-piling, and put in the puddle. This simple expedient, therefore, saved an expenditure of nearly $2,000.

The New Works.—The masonry of the new gate house, culvert, and conduit, is all laid in hydraulic cement mortar, and rests upon a foundation of timber, and 2 courses of plank. Concrete masonry is filled between the timbers, to take their place if they should ever decay, which, as they will always be submerged, will not soon occur.

There was another source of danger which had to be guarded against, viz., that the water would follow along the sides, top, or bottom of the masonry, through the whole width of the leak, and escaping at the lower side, again produce a leak. To prevent this, belt walls of masonry were built at each row of sheet-piling, and one still further toward the gate-house. These belt walls extend 3 feet beyond the outside lines of the masonry of the culvert and conduit on the bottom, on the side, and over the top, and are built up with the other masonry, thus forming a perfect cut-off to the water at each belt. The outer faces of these belts are "toothed," to produce angular obstructions to the water.

THE STRAINS IN GIRDERS.

METHOD OF DETERMINING THEM GEOMETRICALLY.

From the "Building News."

In 1856, Prof. Cullman, filling the chair of Civil Engineers at the Zurich Polytechnic School, published, under the name of "Graphical Statics," a geometrical mode of determining the stresses in structures, which deserves the greatest attention from practical engineers and architects. It is a process in which geometrical construction is substituted for complicated calculations; or, in other words, by which a great saving in time can be effected, together with a self-evident avoidance of liability to error. It will be seen that this process enables the architect or engineer to instantly note the effects of any alteration he may chance to make in his designs. As is seen one example we have chosen is that of the well-known case of a common Warren girder.

The basis of the method is simply that of the almost popularly known principle of the parallelogram of forces. It is well known that a force can be geometrically represented by a *straight* line running parallel to the given force, and denoting the amount of the force by its length. Of course a line *per se* cannot exactly denote a force, but if the course of the force or its direction from (say) right to left be also held to be indicated by the line, then all the required qualifications are given. Let us suppose, for instance, that we have a number of forces acting in a plane upon the same point. We then have, as indicated in the following diagram, to find the resultant of any number of given forces 1, 2, 3, 4, 5, acting upon 1 point, as indicated in Fig. 1:—Draw a polygon O *a b c d e* with its sides 1, 2, 3, 4, 5, parallel to the directions and equal to the magnitudes of the forces. These must be so arranged that if we indicate the courses of these forces in all the sides by arrows, all these arrows must point in the same course round the irregular polygon. The line R, closing this polygon by joining the origin O with the end *e*, represents the required resultant in direction and magnitude. Fig. 1.

This resultant is to be taken in a course opposite to the curve of the given forces. Any one of the diagonals in the polygon represents the resultant of all the forces

Fig. 1.

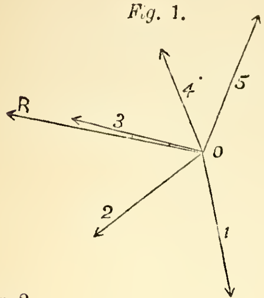

Fig. 2.

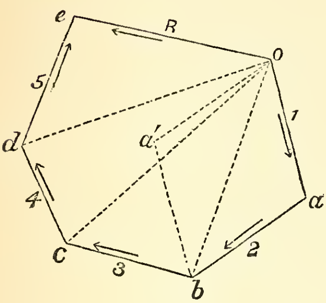

Fig. 3.

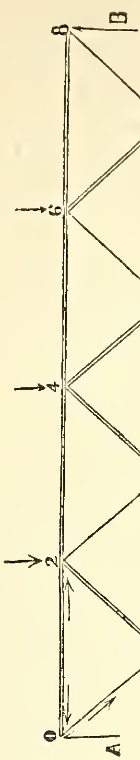

Fig. 4.

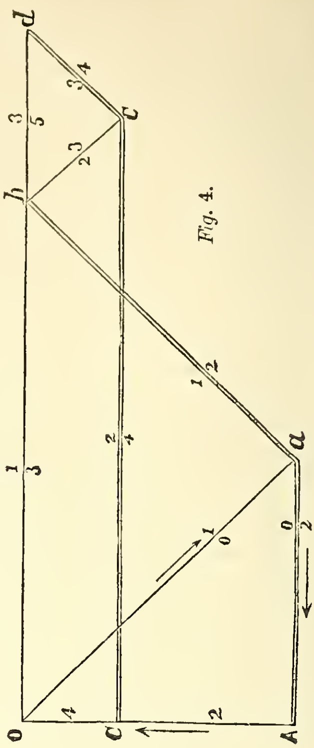


placed between the 2 points formed by that diagonal. This polygon may be termed the "polygon of forces," and it can be proved by successively combining the forces according to the principle of the parallelogram of forces.

If the polygon of any given number of forces, acting upon the same point, is closed, these forces will balance each other; and *vice versâ.* This is substantially the same proposition as that stated by Dr. Rankine, par. No. 53 of his "Applied Mechanics."

To determine 2 forces of given direction so that they may balance any number of known forces, all acting upon the same point, construct the polygon of the given forces and close it by 2 lines parallel to the directions of the given forces. These lines taken in the same direction round the polygon as the others represent the required forces. The second principle is a consequence of the first, and the third is easily proved by the second. With the assistance of these principles it is easy to ascertain the stresses on a Warren girder. To explain the process it will be sufficient to determine the stresses in a small girder constructed with only 4 divisions in the top beam, as shown in Fig. 3. There will be no difficulty in afterwards extending this to larger girders.

We will designate its parts by numbering the connecting points, and by calling each bar lying between them by the numbers at its 2 ends. We assume that the girder is loaded with 10 tons at each connecting point of the top; that is to say, at the points 2, 4, 6; while the resistances A and B of the supports act upon the extreme ends 0 and 8. As the load has been assumed to be uniformly distributed, each of these 2 resistances is equal to one-half the entire load of 30, or equal to 15 tons.

It is a necessary property of any structure that all the forces acting upon the same connecting point should be in equilibrium; and we employ this property to ascertain the stresses in the different bars. If all the forces acting upon such a point are known with the exception of

2, these 2 can be ascertained by means of the last principle stated. We begin at the point O, where the resistance A, equal to 15 tons, acts upwards, and we will proceed to determine the stresses in the bars 0 1 and 0 2, the directions of which are given. We draw the vertical line OA, Fig. 4, parallel to the force A in Fig. 3; and make it, by any scale, equal to 15 tons. The line A *a* is then drawn from A parallel to the horizontal bar *o* 2; and line O *a* parallel to the sloping bar *o* 1. These intersect one another at *a*. Therefore, the lines A *a* and O *a* respectively give the required amounts in tons of the stresses on the bars O 2 and O 1. They are of 15 tons and 21.2 tons. The curves of these forces only remain to be determined in order to know whether the bars have to sustain tension or compression. For this purpose, as we know the course of the force O A, which is indicated by an arrow, we have only to follow round the polygon of forces, which is in this case represented by the triangle A O *a* A, and to draw arrows in the directions in which we follow the sides O *a* and A *a*. By drawing other arrows in Fig. 3 parallel to the corresponding arrows in Fig. 4, we see that the stress in the bar 0 2 in Fig. 3 acts against the point 0; and that the bar 0 2 has consequently to undergo compression. Further, the force in 0 1 strives to pull the point 0 towards 1, testifying to a tensile stress. For the sake of clearness we shall henceforth indicate tension by a single and compression by a double line, both in the elevation of the Warren girder and in the polygon of forces. By this means the course of the forces can be seen both in the elevation and by comparing both figures also in the polygon of forces. We must observe that in the elevation the stress acts on an extremity of the bar in a sense opposite to that in the other.

We now come to the point 1. We have here, besides the last determined force in 0 1, the unknown stresses in 1 2 and 1 3. The stress in O 1 is given in Fig. 4 by the line 0 *a*, and its sense is now contrary to that indicated by the arrow. Proceeding as before, we draw O *b* parallel to 1 3 and *a b* parallel to 1 2, and cause them to intersect at *b*. The lines O *b* and *a b* give the stresses in 1 3 and 1 2 of 30 tons and 21.2 tons respectively. We determine the courses or senses of these stresses from the known sense of 0 1, following round the triangle *a* O *b a* in the direction given by the order of these 4 letters, and we find that the bar 1 3 is in tension and the bar 1 2 in compression.

In the points O and 1 only 1 known and 2 unknown forces were in action; but in the point 2, 3 known forces (the stresses in O 2 and 1 2 and the load of 10 tons) and the unknown stresses in the bars 2 3 and 2 4. To ascertain these, set off from A to C in the line A O the length representing 10 tons and C *c* and *b c* parallel to 2 4 and 2 3. These 2 lines then give the magnitudes of the required forces, because the sides of the polygon C A *a b c* C are parallel and equal to the forces acting on the point 2. They are also taken in the right sense, which is the reverse to the order of the letters C A *a b c* C. We find that 2 3 has to sustain a tension of 7.1 tons and 2 4 a compression of 35 tons.

The same proceeding is to be used at the point 3 4. The 2 known forces (1 3 and 2 3) are already placed together in the right curve in the diagram Fig. 4; they are represented by the lines *c b* O. The lines *c d* and O *d*, drawn parallel to the directions of the unknown stresses through C and O, meet each other in *d* and give the stresses in the bars 3 4 and 3 5, amounting to 7.1 tons and 40 tons respectively. The first is a compression, the second a tension bar. This gives us the strains up to the middle of the girder, and as the girder and the load are symmetrical we do not require to continue the diagram.

This Fig. 4 may be called the diagram of forces. The polygons for each connecting point in the first half of the girder are laid down in it, and, observing how they are combined, we find that the polygons for the preceding points give the forces always arranged as required for the construction of the polygon of forces for the following point. The whole diagram hence contains each force only once, while every line would have to be drawn twice if we construct a separate polygon of forces for each connecting point. What makes this diagram of forces so very useful is that there is a minimum number of lines to be drawn, and that the construction can be rapidly carried out without any liability to error.

SCIENTIFIC SCHOOLS IN THE UNITED STATES.—The Rensselaer Polytechnic Institute, Troy, N. Y.—Civil, mechanical, and topographical engineering and chemistry.

The Polytechnic College of Pennsylvania, Philadelphia.—Civil and mechanical engineering, chemistry, mining, agriculture, and architecture.

The Sheffield Scientific School, Yale College, New Haven.—Chemistry, natural science, engineering, agriculture, mechanic arts.

The Lawrence Scientific School, Harvard University, Cambridge, Mass.—Chemistry, zoölogy, geology, botany, comparative anatomy and physiology, mineralogy and engineering.

The Chandler Scientific School, Dartmouth College, Hanover, N. H.—Engineering, commerce, and general courses.

The University of Michigan, Ann Arbor, Michigan.—Civil engineering, general chemistry, mining, natural history, and general science.

The University of New York city, "Professional Department."—Engineering, architecture, analytical and practical chemistry.

The Washington University, St. Louis.—General science, and technical course.

The Cooper Union, New York city.—Free night-schools of science, of art, of design for women, and a polytechnic day-school.

Brown University, Providence.—Department of chemistry and engineering.

Massachusetts Institute of Technology, Boston.—Mechanical, civil and topographical engineering, practical chemistry, geology, mining, building, and architecture, and higher general sciences.

The School of Mines, of Columbia College, New York city.

Besides the above are the Scientific School of the New York Free Academy, New York city; the Collegiate and Engineering Institution, New York city; the Lehigh University, technical course; the University of Pennsylvania, technical course; the Worcester County Free Industrial Institute, Worcester, Mass.; the Cornell University, Ithaca, N. Y.; the University of the South, Suwanee, Tenn.; the Delaware Literary Institute and Engineering School, Franklin, N. Y., and the School of Mines in connection with Harvard College, Cambridge, Mass.

MENDING HYDRAULIC CYLINDERS.—An engineer in Berlin gives the following as a method of effectually stopping up a porous casting for a hydraulic press. The cylinder is to be heated over a charcoal fire to about 170° Fahr. It is then to be filled up with resin and suspended by a crane over the fire until the liquefied resin is seen sweating through on the outside. The excess of resin is then poured out and the cylinder allowed to cool, when the pores will be found completely stopped, and no water can possibly pass.

OIL CARS AND MOLASSES SHIPS.—As the use of barrels for transporting petroleum is giving place to tank cars, so the hogshead is to be superseded by the tank ship. The Atlantic Works at East Boston are to build an iron brig 350 tons, which will have compartments for transporting molasses in bulk. The saving of space and non-paying load will be very great, and this principle is likely to be carried farther.

LOCOMOTIVE ENGINEERS' CONVENTION.—The October meeting at Chicago was marked, says the "Chicago Railway Review," by good feeling, good sense, and temperateness. The subject of temperance, so vital to this particular calling, appears to have occupied the direct attention of the members, and is specially and hopefully referred to in the president's report.

UNITED STATES RAILWAY CONDUCTORS LIFE INSURANCE COMPANY.—The conductors of several important roads recently started an association thus named, at a meeting in Cincinnati. All conductors of good character may become members. The Secretary and Treasurer is to receive $100 per month, and all claims are to be referred to an executive committee of three.

PHOTOGRAPHING interiors by the aid of the magnesium light is pronounced a complete success. The Prussian photographic commission sent to Aden to obtain pictures of the late eclipse, returned by Egypt, and are obtaining fine copies of the great monuments of art there—among others the interiors of subterranean tombs.

PERMANENT WAY.

Rail Joints.—The introduction of steel rails has been accompanied in this country by an almost equally important and novel improvement—a rail joint. The chair, a mere seating for rail ends, is, let us hope, a feature of the old system that is all passing away. When a road has traffic enough to warrant the use of steel rails, it will pay to make them continuous by means of the fish joint, or its equivalent. The fish joint, after some twenty years of invention and experiment in rail-jointing, has held its own against all competitors. When plates and rails are both of steel, and shaped so that the wear can be taken up, the joint holds fast for years. The difficulty of keeping the nuts tight is now perfectly overcome by interposing a piece of leather, or a washer of rubber. Another important requirement of the fish joint is a well-shaped rail. It is a singular and fortunate circumstance that a rail well adapted to fishing is also well adapted to resisting deflection and wear. The old low pear-headed American rail —wasteful of material and rigid in detail, instead of stiff as a whole—might continue in use if it could be fish-jointed; fortunately it cannot be. The only objection raised against the fish joint for steel rails is that it requires holes to be made in the steel. Punching holes strains the steel and renders it liable to break —repeated experiments prove this. But the holes need not be punched. The loss of material in the fish-bolt hole—in the neutral axis—is of no practical account. If the holes are drilled, the material is not strained. The Pennsylvania Steel Works, and the Troy Steel Works, are introducing machinery to drill steel rails. Holes or nicks in the *flange* of a rail—especially a steel rail—are a hurtful loss of material, where the greatest and worst strain comes, and where loss of continuity can least be spared.

The new Reeves joint—a tight clamp upon the flanges of the rail—is getting into considerable use with steel. The long Reeves chair extending over two sleepers, is also much used with steel—as on the Hudson River road. This is more than a chair, but not tight enough on the flanges to make the track continuous. The authorities are divided as to the proper position for the fish-joint. On the Camden and Amboy, for instance, it is placed upon a sleeper, because, it is said, the joint is not as stiff as the rail, and needs this additional support. On the English roads, and the greater number of our own, the joint is placed between two sleepers to avoid the rigidity—the anvil action occuring when it is placed on a sleeper. If the joint did not *deflect*, the sleeper would do no more harm under it than under any part of the continuous rail. But as the simple fish-joint is not as stiff as the rail, and does yield, placing a chair and sleeper under it aggravates the effect of the blow of the wheel. The addition of the new Reeves joint—the tight clamp on the flanges—to the fish-plates, the whole being suspended between 2 sleepers, would make the rail practically continuous, and would avoid the evil of rigidity.

Earthwork and Bearing Surfaces.—"Engineering" says: Until we have much better earthworks, which, like the foundations of a house, can lie still and support in perfect rest almost any load brought upon them, we can never have mathematically perfect railways, and *until we have these we must tolerate that needless and extravagant increase of resistances* which attends any increase of speed above the lowest rate of motion, an increase from 10 pounds or so per ton at very slow speeds on a level, to 30 pounds or 40 pounds at 60 miles an hour. It is idle to say that we can have no better earthworks than we now have, or that the permanent way can rest no more quietly than it now does even on the best earthworks.

With the best earthwork and ballasting there must be abundant bearing surface of the rails on the sleepers, and of the sleepers on the ballast. Every permanent way engineer knows that the bearing surface is now insufficient to prevent the rails from notching upon the chairs, the chairs from bedding themselves in the sleepers, sometimes half way through, and the sleepers from churning the ballast. Mr. Fowler has found it necessary for the tremendous traffic of the Metropolitan (under ground) railway to abandon the double-headed rail, with its costly accessories of chairs, keys, and tree-nails, and to adopt a Vignoles (American) rail with a base nearly $6\frac{1}{2}$ inches wide, which is fastened to the sleepers by screw bolts. Thicker sleepers will permit the use of longer sleepers, without losing the available bearing now lost in consequence of the springing of sleepers only 5 inches thick. Sleepers 9 feet long, 10 inches wide, and 3 feet apart centres, give 13,200 square feet of bearing upon the ballast in a mile of single way. Sleepers 10 feet long, 12 inches wide, and 2 feet 3 inches apart centres, would give 23,466 square feet, or nearly twice as much.

Steel Rails.—But without steel rails there could have been no great improvement in the construction of permanent way. Steel has proved itself to be incomparably safer than iron; from 5 to 25 times as durable; to make a better and smoother way, offering less resistance to traction, and to permit of the use of still heavier engines—the very heaviest locomotives which the permanent way will bear without undue injury or wear being always the most economical.

The steel rails on trial on most of the leading American lines are showing remarkable endurance, but wear can be detected, and managers are comparing it with the wear of new iron, and calculating that although steel is very satisfactory, it can hardly come up to the alleged endurance of 20 to 1. They should not forget that the defect of iron is not in its abrasion, but in its lamination at the welds. When lamination—peeling once begins, the iron rail, however well it may have resisted *surface* wear, soon goes to pieces. But steel is subject to surface wear alone, it has no welds, and is as *sound* after half an inch has been ground off its tread as it was originally.

As to what is to become of old and worn steel rails, many people are unduly anxious. The "Chicago Railway Review" says: "They are useless after being used for rails." We are not aware that this product is in market, but we are aware that it will bring a much higher price than old iron rails, to be rolled down into small merchant bars and rods. The quality of these products will be better than that of equally good steel, cast in small ingots on purpose for small bars, as they will have had all the work necessary to reduce them from 10 or 12-inch ingots.

The Double-Headed Rail.—Says the "Mechanics' Magazine": The objections alleged against the double-headed rail are that, first, it necessitates the expense of chairs; and that, secondly, the turning of them, in which their chief merit lies, cannot be accomplished universally. If every rail could always be turned, so as really to do the duty of 2, then the increased amount of work got out of the rail would more than compensate for the expense of the chairs, and, *cæteris paribus*, it would prove more economical than the flanged description. To effect this result, two precautionary measures must be undertaken, the one to prevent the unevenesses and asperities which are produced upon that portion of the rail in contact with the chair; the other, to enable the upper head, after being worn, to bed evenly and steadily in the chairs. With the ordinary chair these conditions are not accomplished. The wooden keys which are employed to wedge the rail against the chair allow a small separation to exist under the varying circumstances occasioned by the influence of the weather. Consequently, the passage of a train produces a successive repetition of little shocks or concussions, which give rise, after a certain length of time, to a notching in the lower head of the rail which rests upon the chair. The "Mechanics' Magazine" then describes a new plan of interposing an elastic medium between the rail and the chair to prevent this under wear—a cushion of hard wood placed in a pocket in the chair. The use of steel of course decreases the rapidity of this wear in the chairs.

Other advantages of the double-headed rails are as follows: They are more readily removed and replaced than flat-footed rails, for as they are not directly fastened to the sleepers, all that is necessary is to knock away the keys and fastenings and lift them out of their chairs. Similarly, new sleepers are readily substituted for the worn-out ones, as sleepers and chairs can be removed together, while another, with its chairs fixed on, can be slipped in at once. The manufacture of the double-headed rail does not present so many difficulties as the flanged example, and it can probably be obtained cheaper in the market, especially when made of steel. The double-headed rail is better adapted for sharp curves, owing to the greater facility it possesses for being bent to the required radius. The flange of the American rail, by its comparative large breadth, bends with difficulty, and incurs a greater chance of being weakened and damaged by the operation. This is particularly the case with steel rails.

Iron Sleepers.—Our ways will never be really permanent so long as wood is employed in their construction. The expense of iron sleepers will, however, long prevent their introduction, except on lines of the heaviest traffic, and in countries where wood cannot be obtained much cheaper. The "Railway News" thus describes the various systems: All the varieties of iron permanent way may be reduced to one of the 3 following classes: Firstly, roads carried upon isolated supports, or "pot" sleepers; secondly, those supported by transverse bearers; and thirdly, those carried upon continuous or longitudinal supports. In Egypt, India, Brazil, and other distant countries, pot sleepers have answered well. A Belgian principle consists of a strong horizontal transverse sleeper of the double tee form, carrying 2 wooden blocks to serve as supports for the ordinary rail, of whatever shape it may be.

Three principal lines in France have afforded a fair trial to iron roads, and selected the Fraisans system, which gives a total weight per yard run, including rails and all fastenings, of a little over 2 cwt. The principle of Lecrimer, which in many respects greatly resembles that just quoted, has been laid down for 8 years on some of the Portuguese lines, and it is still doing good service. In Prussia the Hartwitch longitudinal road is employed to some extent. It consists of a pair of heavy contractor's rails, tied by iron transversals, which carry them and rest upon the ground, the flange of the rail having a breadth equal to half that of the height. The same principle has been adopted upon portions of the Lyons Railway, only the height of the rail is made equal to that of its base, which in this instance rests upon the ballast similarly to a Barlow or saddle rail. The system of Barlow is, in fact, identical with that of Bergeron, and so is the iron longitudinal plan that is soon to be practically tried in Austria.

At present it is certain that those iron permanent ways which are based upon the transverse principle have enjoyed more favor and likewise more success than those modelled after the longitudinal method. The desideratum to be insured in all rigid roads similar to iron ones is the imparting of some slight degree of elasticity, not as absolutely necessary for the safety of the road, but to diminish the enormous wear and tear that would be otherwise brought both upon the rails and the whole of the rolling stock.

Broken Rails.—A professional writer in the "New York Times," says: There is a comparatively inexpensive and wholly unobjectionable device for security against disaster by broken rails. We mention it here, not with the slightest expectation that it will be adopted on one mile of our forty thousand, but that the managers and legislators, who are maimed this winter by broken rails, may contemplate what it *might* have accomplished in their case, as they lie in splints all the weary nights.

A stick or plank of oak, as deep as the rail (say 4 inches), and 10 to 12 inches wide, fitted to the outside of the rail, bolted to the rail every 3 feet, and screwed down to every cross sleeper, would, in 9 cases out of 10, if not in all cases, hold a broken rail in place, and so prevent its throwing off the wheels. It would also prevent that other disaster, second only in frequency, but not in frightfulness, to broken rails, the spreading of the track. The timbers should break joints at a place where the rail has both vertical and lateral support on a sleeper. A wooden rail, heavy enough to support a wheel, and tough enough to endure any probable shock without breaking, is thus sandwiched with an iron or steel rail that will endure the wear and sustain the load, but which is liable to snap under a blow, just in proportion to its resistance to flexure and abrasion. Even steel, so remarkable in its wearing qualities, and so superior in strength and toughness, cannot be absolutely guaranteed against breaking. And the harder it is, the better it resists wear and deflection, the more liable is it to break. This is the law of iron and its alloys. Hence the combination of a tough wooden rail with a hard metal rail is in the greatest degree economical as well as safe.

It would be still safer to add also an inside plank of oak, so that the rail would be absolutely sandwiched between the two, and so prevented from displacement, although broken in pieces. This inner plank would, of course, be thinner, to allow room for the flanges of the wheels.

The longitudinal system, a rail spiked down to a continuous timber, instead of bridging cross-sleepers, although objectionable on economical grounds, is vastly safer against disaster from broken rails. A modification of this system, somewhat used in England, and destined, we think, to a more extended adoption, is called the sandwich system, and consists of a deep, thin rail, bolted between two heavy longitudinal sticks, which form the sleepers. A rail thus secured could be broken into bits a foot long without throwing off the train.

The continuous rail, made in two pieces, lying side by side, riveted together and breaking joints, was abandoned because the softness and structural unsoundness of iron unfitted it for the service. Why is not steel tried for continuous rails? One bar should be made extremely soft and tough to resist the blows and strains, the other hard to stand the abrasion.

But while the various plans that require reconstruction have that obstacle opposed to their introduction, the plan we first mentioned of one or more oak planks bolted to the sides of the rails, has, we think, no objectionable or impracticable features. The cost would be from $2,000 to $2,500 per mile. Its saving of damage is likely to be as much, not to speak of its constant and positive addition to the strength and durability of the permanent way, and to economical traction.

Conclusion.—"Engineering" closes the article hereinbefore quoted as follows: Railway engineers and railway companies must and will learn that upon the perfection of the way depends the highest working economy. After expending millions in Parliamentary struggles, millions for compensation, millions upon earthworks, colossal bridges and viaducts, tunnels by the mile, stations of the grandest dimensions and of superb architecture, and millions for costly locomotive and carriage stock, the question of a few thousand pounds more or less per mile for first-class permanent way is not one upon which true economy in working and in maintenance can be sacrificed. There are railways enough which have cost their £100,000 or more per mile, and plenty that have cost £50,000, whereas the difference between the cost of a really good as compared with an ordinary permanent way, the platform upon which all the functions of a railway are really discharged, need not exceed £3,000 per mile.

GEOLOGICAL Negatives.—Mr. James Thompson, of Glasgow, Scotland, has contrived a new method of producing photographic negatives of geological specimens. He saws from the stones thin slices containing fossil remains or other specimens; these when polished are so thin and transparent that they may be used as negatives for photographic printing upon the usual sensitive paper. Beautiful prints are thus obtained, having all the fidelity of nature itself. Large numbers of these fossil negatives have been prepared by Mr. Thompson, and he has undertaken to supply the British Museum with duplicates.

MR. N. SCOTT RUSSELL, son of the famous London ship-builder, is now engineer in charge of Messrs. Baird's works at St. Petersburg. The works produce marine and stationary engines and general machinery; also some 10,000 tons of rolled iron per annum. They employ 2,000 hands.

ZEUNER'S VALVE DIAGRAM.

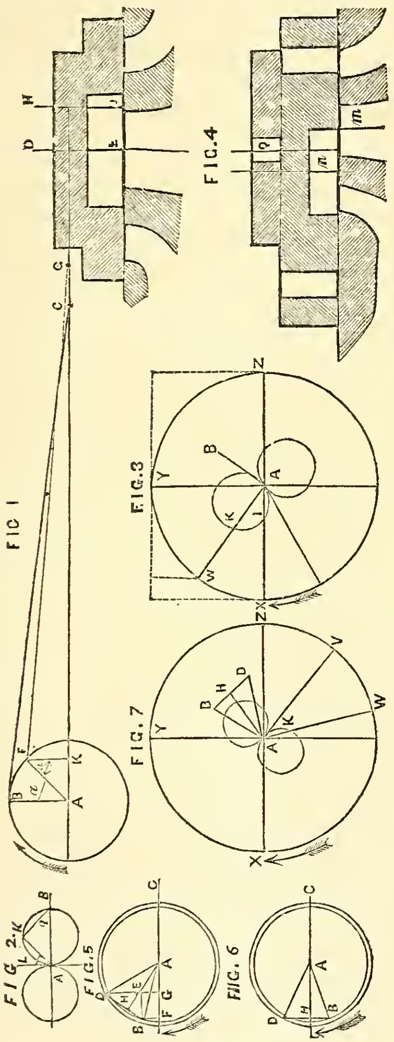
Translated from Zeitschrift des Vereines Deutscher Ingénieurs.

The great value of Zeuner's diagram for explaining the movements and construction of steam valves, induced the author to bring it within the limits of his lectures on mechanics, at the Polytechnic School at Saarb-in-Vien. But the want of the knowledge of the higher mathematics amongst those addressed, did not allow him to give the same investigation as is published by Professor Zeuner in his excellent book on valve gears; a more simple and elementary explanation was required, and this was obtained for the ordinary valve as well as for Meyer's expansion gear in a very simple manner. The author brought it before a meeting of the Society of Engineers at Saarb-in-Vien, and a favorable reception as well as the express wishes of the members encouraged him to bring it before the general public.

The chief point of Zeuner's method

consists, as is well known, in the determination of a simple figure, composed of straight lines and circles, by which the corresponding position of the valve, for any position of the crank or of the piston, may be easily ascertained.

In the following, the construction of the diagram is only confirmed in an elementary manner; as regards its prac-



tical application, the above-named book may be itself used.

A. *The diagram of the simple valve gear.*

Most valves are moved by eccentrics or cranks, and in order to simplify the expressions used, the latter may be supposed. This is correct, as an eccentric produces the same movement as a crank correspondingly fixed, and of which the radius is equal to the eccentricity of the eccentric. In Fig. 1, let

A=the centre of the driving axle.

AB=the valve crank (eccentric) in its central position.

BC=the eccentric rod.

CD=the valve rod as far as the valve centre D E.

If now the crank moves from the position A B into another one A F, the corresponding position, H J, of the centre of the valve is obtained by describing from the point, F, with the length of the eccentric rod, B C, as a radius, an arc, and from the point, G, where this arc crosses, A C, marking the length of the valve rod to the centre of the valve, equal G H. B C is in practice always very long in proportion to A B, and A C may be therefore, without committing a great error, taken as equal to B C, and F G equal K G; then A K is also equal to D H, if F K is perpendicular to A C, or the movement, D H, of the valve from its central position is equal to the base of the right-angled triangle, A K F, of which the hypotenuse is always equal to the crank radius, A B, and of which the acute angle, A F K, is equal to the angular movement α of the crank.

But all right-angled triangles with the same hypotenuse may be placed in a circle, of which this hypotenuse forms the diameter; constructing therefore a circle with the crank radius, A B, as a diameter (Fig. 2), drawing next the tangent, A L, and laying on it the angle, L A K$=\alpha$, from Fig. 1; the equality of the triangles A K B (Fig. 2) and A K F (Fig. 1) can very easily be proved.

The movement of the valve from its central position corresponding to any angular movement α of the crank, is thus very simply obtained, as the chord of the arc, A K (Fig. 2) by laying off the angle α from the tangents A L. Fig. 2 gives at first only the movement of the valve centre towards the right hand side, for the values of α between 0 and 180°; but by a symmetrical construction of the circle, A K B, upon the other side of the tangents, the corresponding movements of the valve towards the left hand side are obtained in a similar manner.

Now it will be easy, by means of the circles obtained in Fig. 2, and which may be called briefly valve circles, to construct a diagram, which will show for any position of the piston crank the corresponding position of the valve. In Fig. 3, let A X be the piston crank on the dead point, and A B the valve crank in the corresponding position, and X Y Z the crank pin circle. If the angle Y A X is made a right angle, and the angle X A V equal to B A Y, then the valve crank will be in the position A Y, *i.e.*, in its central position, when the piston crank A X stands in the position A V. Drawing now the valve circles, as constructed in Fig. 2, so that in Fig. 3 they touch the line A V in A; the corresponding movement of valve from its central position for any other position, A W, of the piston crank, will be equal to that part, A K, of the radius of the piston crank, which is also a chord of a valve circle; and it will be seen at once, that the valve crank, when the steam crank is in the position A W, has travelled from its central position through the same angle, V A W, through which the steam crank has travelled during its movement from A V to A W.

B. *Expansion gear with 2 valves.*

The valve gear, represented in Fig. 4, is one with an expansion and distribution valve. Let m be the centre of the exhaust port, n the centre of the distribution valve, and o that of the expansion valve. From what has been already said, it will be easy to determine for any position of the piston crank—the corresponding positions of the centre n, with regard to the centre m, and that of the centre o, with regard to the centre m; it is, however, of importance to ascertain in a similar manner the reciprocal positions of the centres n and o. Thus, in Fig. 5, let A B be the eccentric or crank for the distribution valve in any position, and A D that of the expansion valve in the corresponding position, whilst A C may represent the axes of the valve rods. If B F and D G are penpendicular to A C, then A F represents with sufficient exactness—according to what has been stated previously—the movement of the distribution valve from its central position, and A G that of the expansion valve, and it will be thus easily seen that F G represents the distance between the centres of the 2 valves. Drawing now also B E perpendicular to D G, then F G= B E, and the distance between the 2 valve centres is again given by the valve B E as the base of a rectangular triangle B E D, of which the hypotenuse is constantly equal to D B, or to the distance between the crank pins of the 2 valve cranks. If A H is drawn perpendicular to B D, the angle B D E of the rectangular triangle B E D will be equal to the angle H A F, for the sides of the 2 angles are perpendicular to each other. Supposing now the line A H to be fastened to the 2 valve cranks, and the latter to be rotating, the shape of the rectangular triangle, B E D, will be determined by the known hypotenuse, B, and the corresponding value of the angle, H A F. The shape of the figure is, as for example in Fig. 6, drawn for an angle H A F=0; the projection from B D upon A C is then *nil*, or the centres of the valves coincide.

It is now easy, in an analogous manner, to represent, as a chord of a circle whose diameter is B D, the movement of the valve circle for any value of the angle H A F. For if, in Fig. 7, A is the centre of the piston crank, and A X its position at the dead point, if next A B and A D are the corresponding positions of the cranks or eccentrics for the distribution and expansion valves, and if A H is perpendicular to B D, then suppose the axle to be turned back through the angle H A X, and A H will fall upon A X, or the valve centres will coincide, and the corresponding position, A V, of the steam crank will be found, when angle X A V is made equal to angle H A X.

Drawing now the two circles, of which the diameters are equal to B D, so that they touch A V in A; for any other position, A W of the crank, that part A K of it, which is situated as a chord in one of the circles, will represent the corresponding distance apart of the valve centres. The accuracy of this will be seen, if we consider that, while the crank passes through the angle V A W, the line A H removes at the same angle from A X.

SHODDY GOLD is made of 100 parts pure copper, 17 of pure tin, 6 of magnesia, 9 of tartar of commerce, 1.6 of unslacked lime, and 3.6 of sal-ammoniac.

COAL MINING.

VENTILATION—MINING WITHOUT GUNPOWDER—SAFEST METHOD OF WORKING.

Condensed from the inaugural address of Mr Elliot, President of the North of England Institute of Mining Engineers.

With regard to the duration of the coal supply in Great Britain, Mr. Elliot said: I have no hesitation in expressing my opinion that it depends in a great degree upon the scientific improvements we are able to make in our mode of ventilating the workings. It is probable that the ordinary means of ventilation—whether by furnace or fan—may be aided by a change in the force or agency employed for the purpose of haulage and other underground work. As an instance of my meaning, I may mention that the apparatus which I have introduced in South Wales, and which by means of compressed air used as a motive power instead of steam, draws trams and pumps water with complete success, is found to generate ice in an atmosphere which is naturally hot and oppressive. The mechanical usefulness of these new air-engines seems capable of indefinite extension; while, as their cooling properties form a collateral advantage arising out of their use, it is at least possible that they may prove valuable auxiliaries to the more regular means of ventilation in extending the security and promoting the healthfulness of our mines.

The difficulties of ventilation once surmounted, the extent of coal at our disposal is incalculably increased. The fields to be worked below the sea on our east and west coasts are in themselves enormous, and will be for all practical purposes as entirely within the reach of the mining engineer as the ordinary workings out of which coal is hewed. Geology indicates that in many districts the coal strata extends seaward 10 or 12 miles beyond the shore; and it is my firm belief that by sinking ventilating shafts in the German Ocean, the coal below it may be worked as safely and certainly as it is beneath where I am now standing. Nor do I recognize any difficulty in the transport of such coal. According to my estimates, it would neither be more costly nor more laborious than it has been in days gone by to convey coal the same distance after it was brought to the surface inland.

Mr. Elliot's next proposition aims at revolutionizing the system under which coal is worked. He says: It is simply that we should abolish the use of gunpowder in our mines, and by so doing reduce the number of deaths from colliery explosions to a minimum. For more than a quarter of a century I have steadily looked forward to this end; have upon all favorable occasions agitated the subject among my engineering friends; have tried divers experiments; and have watched and tested with earnest interest inventions which had the disuse of gunpowder for their aim. Nearly 20 years ago, while giving evidence in the House of Lords, I suggested that the Government should offer a premium to any one who succeeded in making such discovery. It should never be forgotten that the existing necessity for the use of gunpowder is the fruitful source of colliery accidents; once abolish it, and the need for naked lights is gone. Safety-lamps might be devised which the pitmen could not open. At present the phrase "safety-lamp" is a misnomer. No lamps yet invented are entirely safe. A series of experiments, tried several years ago, showed us that at a certain velocity the flame passed all the lamps in existence; and until it is possible to send our men into the pits with enclosed lights and cases which are immovable, we shall not have grappled with the difficulties arising out of the fire-damp and gas.

The substitution of mechanical means for blasting by gunpowder is, however, fraught with difficulty. Our early experiments were not successful; we endeavored to burst down the coal with quick-lime and other substances, but failed in every instance, owing to the slowness of the operation. I have tried, moreover, to force down the coal by hydraulic machinery, but failed also, through the water percolating into the coal and exhausting itself by that means. I have, however, the satisfaction of knowing that our labors have not been altogether lost, for their results having been sedulously made known among my younger engineering friends, they in their turn have brought their energies to bear upon the point, and with considerable success. I have recently seen 3 kinds of appliances for this purpose, some of which are being worked at this moment in my collieries in South Wales, and, according to the latest reports, working well. My conviction is, therefore, that mechanical means will very soon make the use of gunpowder unnecessary; that lights which it is possible to explode will, in consequence, be banished from our pits; that our coal will be produced in a far better condition, as well as at comparatively little risk to human life.

As a general rule, pits of a less depth than from 60 fathoms to 80 fathoms are almost free from gas; at from 80 fathoms to 180 fathoms deep, gas is most dangerously prevalent; after the last limit has been passed, the workings down even to 300 fathoms, again become comparatively pure. A feasible reason for this singular gradation is that, in the zone first named, the gas has a natural vent at the mouth of the pit, and by means of the various strata through which it can filter to the surface. At the middle zone, or point of greatest danger, the gas has not the same means of clearing itself, while that generated there is augmented by the gas ascending from the greater depths, and the aggregate amount stagnates, to the increased peril of those working in it. Another reason is, that the gas generated in coal at the lower depths is increased in heat, owing to the additional weight of the superincumbent strata. The heightened temperature causes it to expand and ascend, and so find its way to the middle distance, which becomes surcharged. I have found that in this zone (80 to 180 fathoms) a sudden fall of the barometer produces a greater increase of gas than in either of the others—another proof how much more it is charged.

In the zone nearest the surface the working of seams one above the other has not the same effect as in the other two. But by working seam over or under seam at the middle distance, and at the greatest depths of all, a wonderful improvement takes place in the condition of the coal. The lateral workings provide the gas the same opportunity of escaping as at the least dangerous depth. It finds its way through the strata from the opening out of the seams above and below, just as it does to the surface in the first zone. The result is that coal, which when it is first reached is soft and crumbly, becomes hard and firm, and workings which were originally surcharged with gas are made purer and more safe as the seams above and below them are displaced. At Monkwearmouth, Usworth, and other deep pits, the general improvement from this cause has been very marked. We here see that the principle on which many of our colliery leases are granted is erroneous. These contain stipulations that all upper seams shall be worked first. But the clauses, designed as they are to preserve the coal and avoid loss, defeat the object in view. To work seam under seam and over seam concurrently, is advantageous both to lessor and lessee; it insures a purer atmosphere underground and a better condition of coal, and therefore merits the advocacy of all interested in our coal-fields and the extent of their supply.

COMPOSITION OF STEEL.

Gruner in Annales des Mines and Berg und Hütten Zeitung.

Translated by John B. Pearse.

What is steel? This is a question which has of late been frequently discussed, while a satisfactory solution is rendered diffiult by conflicting definitions of the word steel, the distinctions of which are too often rather theoretical than practical.

Experience proves that pig and wrought-iron may be produced from any ore with great facility, and that the products vary in quality according to the impurities of the ores, and the methods of reduction, as the latter do not remove all impurities in equal proportion. These products may be soft or hard, cold or red-short, brittle or tough, but are called pig-iron or wrought-iron as the case may be. To all products which do not come under one or other of these heads the term steel may be justly applied. Pig or cast-iron is the raw product of the reduction of the ore, and may be hardened when chilled quickly. Wrought-iron includes all iron pure and impure, and made either directly from ore or by operating on pig-iron; wrought-iron is malleable cold and hot, but cannot be hardened. Steel occupies the middle position, and while it remains entirely malleable may be hardened. It is, then, difficult to say where the line shall be drawn, as the series of products is an unbroken one from the most graphitic impure pig-iron to the purest and softest wrought-iron. Cast-iron merges into steel, and becomes slightly malleable, and steel becomes soft and similar to iron in many of the products classed under the heads of puddle or simmer steel, etc.

These differences may be remarked as well in the chemical constitution of the respective materials. It is, however, difficult to determine the exact amount of each element present, as the quantity is so small proportionally to that of the iron. Experience shows, however, that the same foreign elements show themselves in the pig-iron, the steel, and the wrought-iron. We find that the same products, varying only in purity, may be prepared from any ore, and therefore consider it proper to take it for granted that these various forms of iron are due to the relative amounts of carbon and other elements present in them. It has long been known that all metals are materially affected by small amounts of foreign elements, and no exception to the rule is possible in the case of iron.

Copper is greatly affected by traces of oxygen, sulphur, or lead; and a few thousandths of a per cent. of iron reduce the ductility of both zinc and tin. Fremy has shown that a trace of bismuth or lead makes gold as brittle as antimony. It is further known that chrome, nickel, turgsten, etc., harden iron similarly to carbon.

The substances which are associated with iron are, however, more numerous than is generally believed. The following may be mentioned: Carbon, silicium, phosphorus, sulphur, arsenic, potassium, sodium, calcium, magnesium, aluminium, manganese, nickel, chrome, titanium, vanadium, copper, nitrogen, and sometimes cobalt, molybdanum, etc. It may be asserted with justice that pig-iron contains some portion of every element present in the ores from which it has been derived.

The presence of nitrogen has been shown to be without any influence on the formation of steel as Fremy supposed, and the quantity of the same in steel has been shown to be so small that its very presence has been reasonably doubted. Aluminium is present in all irons smelted from clay iron ores or any of the varieties of black band; these irons contain also calcium and magnesium. Some analyses render it probable that the silicium present in gray irons rich in manganese is probably chiefly combined with the latter; the probability of such a combination is made stronger by the results obtained by Brunner and Wöhler, who found that manganese may be readily alloyed with $\frac{1}{12}$ per cent. of silicium.

Gray iron often contains more than 10 per cent. of foreign constituents, the number of which is very great. This is especially the case when the iron is very graphitic and has been reduced at a great heat. Fresenius' analyses show that white iron (spiegeleisen) may contain nearly 18 per cent. of other elements, manganese and carbon with silicium being always in preponderance. These elements are reduced along with the iron even when the latter is produced at the lowest possible temperature, as is the case with a number of the Styrian white irons.

Elements present in the fluxes are reduced into the iron, as for instance calcium in considerable quantity when much lime is used with clayey ores. Therefore it may be stated as a general truth, that pig-iron contains some part of all substances present in the furnace at the time of its reduction.

With reference to the elimination of these substances, experience proves that only those elements may be entirely eliminated which possess at the same time a great affinity for oxygen and a weak affinity for iron. These are manganese, calcium, magnesium, etc. Deville has shown that aluminium is less readily ozidizable, and that it is present in some varieties of steel. The majority of the varieties of steel contain in addition, sulphur, phosphorus, silicium, and copper; some French steels contain also cobalt and nickel. Parry shows that the puddled steel made at Ebbwvale contains carbon, silicium, sulphur, phosphorus, and manganese, and Karsten proved long ago that the four former are contained in every variety of wrought-iron. The composition of steel and wrought-iron is then quite as complicated as that of pig-iron, the proportions only of the respective elements being different.

The element which takes precedence of all others in its influence on the properties of steel is carbon. The results of the investigation of many kinds of Swedish and Styrian Bessemer steel show the great influence of carbon on the respective hardness and elasticity. In Sweden, 9 sorts of Bessemer steel are distinguished (Boman), and numbered 1, 1½, 2, 2½, 3, 3½, 4, 4½, 5, beginning with the hardest. Analyses made at Silianfors give the corresponding percentages of carbon as in round numbers :

No.	1	1½	2	2½	3	3½	4	4½	5
	2	1.75	1.50	1.25	1	0.75	050	0.25	0.05

per cent. carbon, which percentages corresponded to fixed characters and varieties of the steel. The absolute worth of the steel depends also on the number and amount of injurious elements present. It is probable that steel made from English and French pig-irons should contain less carbon than Swedish or Styrian steel, in order to possess the same welding or hardening qualities.

Tunner gives the following assortment of Styrian steel: Nos. 1, 2, 3, 4, 5, 6, 7, with respectively 1.50, 1.25, 1.00, 0.75, 0.50, 0.25, 0.05 per cent. carbon. Tunner had estimated by practical tests the carbon content of the respective numbers of the assortment exhibited by the Heft Works at Paris, and stated them as follows : For Nos. 2, 3, 4, 5, 6, 7, Tunner stated respectively, 1.35, 1.15, 0.85, 0.72, 0.53, 0.11 per cent. of carbon, while analyses made at Heft showed that Nos. 3, 4, 5, 6, 7, contained respectively, 1.10—1, 0.85—0.75. 0.42, 0.25 per cent. of carbon.

A series of Neuberg bars exhibited at Paris, contained for Nos. 1, 2, 3, 4, 5, 6, 7, respectively, 1.58—1.38, 1.38—1.12—1.12—0.88, 0.88—0.62, 0.62—0.38, 0.38—0.15, 0.15—0.05 per cent. of carbon. These figures show that 0.25 per cent. of carbon suffice to change the steel of one grade into that of another. They fully corroborate the old theory, according to which the grade of steel is proportioned to the percentages of carbon, other circumstances being the same. The latter reservation is necessary as other substances besides carbon affect the hardness of steel, and the facility with which it may be welded. Nevertheless it is perfectly correct to state that the qualities of steel depend principally upon the percentage of carbon.

The classification of steel has been studied with care, especially that of Bessemer steel, in order to be able to supply all qualities suited to every industrial requirement. In the course of these experiments many interesting observations have been made, among which that of Vickers, that the toughness of steel decreases as soon as the percentage of carbon exceeds 1.25 per cent., is especially interesting.

These data considered collectively show that the iron and steel and pig-iron of commerce are similar compounds of iron and carbon, which always contain other elements ; further, that the qualities of the individual varieties depend chiefly upon their purity and the proportion of combined carbon, and finally that an unbroken series of products connects the softest iron, with the least carbon, with the different kinds of steel, and these in turn with pig-iron. In white iron and hardened steel all the carbon is combined, while some carbon is present in an isolated state, as graphite in gray iron and unhardened steel. The exceptions to these observations seem to be very few.

Caron has lately shown that hammering produces an effect on the kind of carbon present similar to that produced by hardening the steel, and therefore supposes that hardening facilitates the combination of the carbon with the iron. I should prefer to believe that the hammering as well as the hardening prevented the separation of two bodies already combined. It is evident from existing data, that both in the blast furnace and in the cementing process iron takes up carbon in proportion as the temperature has been high and long continued ; if, on the contrary, the temperature is reduced slowly some graphite separates. The molecules of soft bodies require a certain time for motion. If the body is suddenly cooled the carbon cannot isolate itself. In my opinion, hammering causes the same result, because it prevents the iron and the carbon from crystallizing, as it were, separately in cooling, but forces all parts with great power into and through each other. A proof of the want of harmony in the effects of hardening and hammering lies in the fact that hammering increases, while hardening decreases the specific gravity of steel.

CORLISS ENGINES.—One of 150 horse-power, recently started for the Meriden Britannia Company, saved in a week's trial 41.8 per cent. of coal over an engine of the old-fashioned kind, with a considerable increase of load. Such results are so common in the history of the Corliss engine, and coal is so costly in New England, that it is a little singular to find so many "old-fashioned" engines still building and running there.

PROGRESS OF THE METALLURGY OF IRON DURING THE LAST CENTURY.

Translated from Berg u Hüttenmännische Zeitung, by John B. Pearse.

Extract from a prize essay by R. F. Stalsberg of Kongsberg, Norway. Part relative to the blast furnace.

Smelting with Coke.—The devastation of whole forests occasioned by improvident use of wood without replanting, necessitated this step. The production of iron in England diminished on account of the scarcity of fuel by about 90 per cent. between 1612 and 1740. Dudley substituted coke for charcoal between the years 1620 and 1650, but was not successful on account of the opposition of other ironmasters; it was, therefore, left for Abr. Darby to bring coke into use between 1735 and 1740, whereby the iron trade received a powerful impetus. The use of coke did not spread so quickly on the continent of Europe, partly because wood was plentiful, and partly on account of the quality of the products. The introduction of coke had become general, however, before 1820, since which time the production of charcoal iron has almost entirely disappeared in Belgium, while in Prussia it does not amount to one-tenth of the iron produced; in Austria the greater part of the iron is made in charcoal furnaces, many of which also still exist in the United States, while they are the only variety in use in Scandinavia and Russia, and it is only recently that coke has been tried in Sweden.

Although the production became vastly larger, the quality of the iron suffered, principally from sulphur and silicium; but it has been found that with ordinary care a first-rate iron may be produced. A partial use of coke or anthracite along with charcoal yields a cheaper iron, the quality of which does not seem to be materially impaired.

Use of Hot Blast.—Forty years ago it was generally believed that the cold blast was the best on account of the greater quantity of air forced into the furnace in a given time. Neilson introduced the hot blast at the Calder Iron Works in 1830, and in 1835 there were no more cold blast furnaces at work in Scotland. On the continent its use became general, but for a while it fell into disrepute because the quality of the iron was made poorer, so that it had been almost abandoned again, especially in Belgium, before 1843. It was found, however, that the cause of the difficulty was not the elevation of the temperature of the blast, but the retention of the old methods of working and proportions of flux, etc. On this discovery its use became general, and the temperature of the blast has been steadily rising till in some places it now reaches 1,000° or more. The high temperature has been found to render the working of the furnace more regular, and to save a great deal of fuel. The reduction of quality by the larger percentage of silicium incident to the greater heat, may be almost obviated by a proper variation of the fluxes and ores. Experience has shown that high temperature in connection with proper fluxes reduces the amount of sulphur in iron, while the reduction of all phosphoric compounds in the ores, etc., is practically as complete with the cold as with the hot blast.

Use of Furnace Gases.—The French developed their use from 1809 to 1836, but the most material progress was made by Taber du Four at Wasseralfingen in Würtemberg, who applied or attempted to apply them to almost every use to which they have since been put, among others to that of puddling. For the latter and similar purposes the temperature produced by their combustion is insufficient. They are almost exclusively used for the production of steam and heating the blast. There have been many doubts as to the economy of their use, but these have been gradually dispelled by experience. There are many methods of closing the furnace top, the best of which allow the gases to collect over the top of the materials, and draw them out in the centre instead of on the sides, such are those of Coignt in France and Langen in Germany. It is probable that the difficulty experienced at several works on closing the furnace top to draw off the gases, and the consequent increased make of white iron, might have been due to other causes than the closing of the top. Wherever the gases are used they should be drawn out of the furnace by a chimney draught, which, however, should be no more powerful than is necessary to overcome the resistance offered by the apparatus to the free passage of gas.

Substitution of Wood and Coal for Charcoal and Coke.—Wood has been substituted for charcoal with entire success;

the cost of carriage is, however, greater than that for charcoal where both must be hauled. For common purposes the use of raw coal is advisible; when, however, good quality is desired, especially freedom from sulphur, it seems best to coke the coal. The advantages of the use of both wood and raw coal are chiefly that the yield in charcoal and coke respectively is increased, and that the volume of the resulting gases is greater while the heating powers of the same are more considerable. The use of raw materials cooled the furnaces at first considerably, and for some way down from the throat; this difficulty was overcome by the use of the hot blast, and so enlarging the upper parts of the furnace that they might correspond in capacity to the increased dimensions of a given weight of wood, and that where coal was used they might permit the free passage of the ascending gas. In England raw coal is the fuel most generally used ; on the continent, however, it is seldom used, and never without admixture of coke. Wood has been in several instances used entirely without charcoal, but as a rule air or kiln-dried wood is mixed with charcoal in various proportions. In some localities in Austria peat is substituted for charcoal, even to the extent of two-thirds of the whole amount, while in America anthracite is sometimes used with charcoal.

The economy resulting from the use of raw fuel is considerable, but the quality of the iron made with raw coal is often seriously injured. Iron made from wood is quite as good as that made from charcoal. There are some coals, however, which can be used raw in the furnace, though they do not yield good coke.

Increased Size and Changed Dimensions of the Furnace.—The small size of the furnaces in use early in the century was doubtless due to the use of charcoal and an inadequate pressure of blast. On the use of coke, etc., the furnaces were enlarged, but principally by increasing their height ; the old form, with narrow, perpendicular crucible, flat boshes and small throat, was long retained as the best construction. In 1820 the crucible was widened considerably in England and Sweden, and its sharp angle with the boshes cut away (1820–1830), while the throat was greatly widened, even up to three-fourths the diameter of the shaft at the top of the boshes. The propriety of the comparatively wide throat is now generally acknowledged. The general form of the shaft is either that of one cone inverted upon another, with more or less cylindrical space between them, or that of an ellipsoid. The application of cylindrical shafts has remained almost local, and the great widening of the throat proposed by Truran has met with no approval : the elliptical form proposed by Alger has not as yet given any very extraordinary results. Rachette combined the ideas of Truran and Alger in his ingenious furnace. This furnace is reported to work well in the Ural Mountains, but the only one built in Europe (for smelting iron) has not as yet been more economical of fuel or allowed a greater production than the old form. The experiments with these various forms are probably not yet ended.

Improved Roasting of the Ores.—Roasting in heaps has been generally superseded by that in variously constructed kilns. In Sweden and Styria the furnace gases are advantageously used to roast the ores. Comparative trials made at various works on the advantages of burnt over raw limestone have led to the use of burnt limestone. These improvements have increased the yield and economy of fuel, while they have greatly added to the certainty with which it is possible to work a furnace.

Perfection of Machinery and Apparatus.—Increased size has necessitated more powerful blast engines, some of which are of enormous size, and furnish wind at very high pressures. The increased width of throat made it necessary to perfect mechanical appliances for charging. These consist in general of a section of a cone inverted over the throat, with the small end down ; the opening may be closed either from below by means of a bell, which is lowered (Parry), or from above by means of a cylinder, which is raised (Langen) to allow the materials to fall into the furnace. These charging arrangements also serve to collect and draw off the gas, that of Parry indirectly, as it merely closes the throat, while that of Langen is so arranged that the gases are drawn directly from its centre.

Utilization of Cinder from Puddling and Heating Furnaces.—(Tap and flue cinder.) Large quantities of iron were yearly lost in these cinders, before they were re-smelted. They should be roasted to facilitate reduction, and should be smelted with a large percentage of lime. The iron made of them is usually very cold short, and is used to mix with better irons in the puddling furnace, and seldom for casting, to which purpose, however, it would be well fitted, on account of its percentage of phosphorus, as it would run thinly and yield sharp castings.

FREIGHT LOCOMOTIVES

Compiled from "Engineering" and "The Railway News."

The present problem for great railways is how to accommodate an enormous freight traffic economically, and also in combination with frequent passenger trains at high speed. To lay other lines for the convenience and safety of passenger traffic, as has been proposed, would be to still farther lose the use of permanent way, already too little worked to pay proportionate interest on its cost. And where is the money coming from to build the other lines?

The theory and the modern practice are in the direction of longer trains, and consequently heavier engines. On the Northern of France Railway, for instance, there are tank engines of 59 tons which haul trains of 45 laden coal trucks on gradients of 1 in 200. Long, heavy trains are worked at less cost per ton carried than light trains, and railway managers generally are making the trains as heavy as their engines can handle, and constantly increasing the weight of their engines. In short, if 1 locomotive can be made to do the work of 2, it is needless to say that an immense economy would be effected in the working of our railway system. If the total working expenses with 20 freight trains of 35 cars each were 75 cents per mile in each direction daily, it would probably be found that for 14 trains of 50 cars each they would not exceed $1, the total cost for all trains being $2.40 per mile in the former case, and $2.24 in the latter.

But will the permanent way stand this increased weight of engines? Steel rails have to a great extent rendered this practice feasible, but steel rails will wear out in time, and the strains of heavier engines, *as now constructed*, upon themselves, and the sleepers and ballast, are very great, and have, perhaps, reached their practicable limit. The purely locomotive engineer is not so apt to see these facts as is the civil engineer, and especially the permanent way engineer. The former looks upon the permanent way as a camel's back, fitted to bear any and all burdens, burdens which no final straw can break.

To insure economical maintenance of way, the *weight upon engine wheels must be diminished*, or at least not increased, if engines are made heavier. The permanent way must be twice as strong to bear 6 tons on a wheel as would be necessary for 3 tons—earthwork, ballasting, sleepers, chairs, and rails—everything, must be twice as strong. And so it must be if but 2 or 4 wheels of all that are in a train press with a force of 6 tons each, and the 100 or 200 others are loaded only to half that weight. The line must be made for the maximum, not for the average nor the minimum load per wheel. The wear or abrasion of the head of the rail is not, it is true, dependent merely (although it is to some extent) upon the maximum load per wheel, and probably 2 wheels loaded to 3 tons each will cause nearly as much superficial *wear* as 1 loaded to 6 tons, although they will knock the way to pieces to a far less extent. Another fault of the existing types of engines is that the weight per wheel but seldom approaches anything like equality on all the wheels. Of 6-coupled engines, the leading wheels may be loaded to 7 tons each, while the trailing wheels may bear only 5, although 6 on each of both would be preferable.

The only way to diminish the weight per wheel of a heavy engine is, necessarily, to increase the number of wheels. It is, then, naturally asked, Why not attach 2 engines to the train? Two engines, however, require 2 drivers and 2 firemen, and a good deal of care to start and work in concert. But, then, there is the plan of working 2 engines footplate to footplate, with but 1 driver, and possibly but 1 fireman. The objections to this plan have been frequently pointed out, and there is but 1 line, the Turin and Genoa, where it has ever been resorted to. The driver's attention, sufficiently occupied with 1 engine, is divided between 2 of every lever, handle, rod, or whatever else he ordinarily has to touch—2 regulators, reversing levers, brakes, steam gauges, glass gauges, dampers, and steam blowers in chimney, 2 sets of pumps, safety valves, cylinder cocks, blow-off cocks, and sand boxes—at least 24 distinct claims upon his attention, where, with any ordinary engine, he would have but 12.

The 59-ton engines on the Northern of France, before referred to, have 12 wheels and 4 cylinders, 2 to each group of 6-coupled wheels. But these distinct groups are not bogies, all the axles being parallel, although the first and last axles of each group have considerable end play. The wheel base, therefore, is nearly 20 ft. long, and the engines thus strain the way laterally, and are often breaking their axle boxes. In any case such engines, having, too, all, or nearly all, the complication of the double bogie engine, must work with considerable friction.

The defects of the modern freight engine are metaphorically depicted by "Engineering" as follows: The locomotive of 1868 is a monster which all good engineers should unite to destroy. He is the stalking horse of railway bankruptcy, the gaunt steed of railway ruin. We can remember the locomotive shortly after he was foaled, and when, as a colt, he beat the devil's tattoo with his little wheels—heels we mean—weighing not more than five tons on the hind pair; and he was a 4-footed locomotive then, and not a 6 or 8-footed nondescript as now. Bless his little boiler! He could, as he was then, ride on the footplate of the hard-mouthed stallions that tear over the rails now, and *they* would never feel it, although the race-course 'yclept "permanent way," might. But he has grown altogether too big, and he must either have more legs put under him or else be knocked on the head. There is a main pair of legs to every engine, through which it must exert all its strength on a pull. For a strong pull all the legs must pull together, and all must keep exact step with each other. This can only be secured by means of certain harness known as coupling rods; but when more than 6 legs at most are coupled, there is fretting and chafing. What with the difference in shoeing, and in the weight on each pair of legs, there is a constant tendency to get out of step, which only the coupling rods can restrain. When the beast has 8, 10, or 12 legs, as some of them have, coupling rods may be carried altogether too far. The weight is well distributed, no doubt—say to 4, or, at most, 5 tons on a hoof—but the coupling rods do almost more harm than good, and in turning Tattenham Corner, or, in other words, a sharp curve, the off heels are playing mischief with everything on that side. The fact is, very long-bellied horses, of the breed we are dealing with, will never ride well.

Dropping the metaphor, 8, 10, or 12-coupled engines, having, therefore, necessarily long wheel bases, tear the way to pieces and themselves too. And the system of engine building which requires a permanent way twice as strong as it is necessary for the paying load, including wagons, to be drawn, is, on its face, wholly wrong, and nothing but habit and an almost pagan veneration for the outward form of the locomotive as George Stephenson left it, can account for the long continuance of a practice so palpably vicious. With properly constructed engines the permanent way need not be made nearly so strong as now, or, if the present strength were retained, the wear and tear, upon the plainest principles of action and reaction, would be very sensibly diminished.

The double bogie engine of Mr. Fairlie appears to meet the modern requirements better than any scheme that has been put forward. The double bogie engine, originally made, in a somewhat different form, many years ago, at Seraing, in Belgium, had many defects in detail which condemned it. In Mr. Fairlie's engine there has been found no serious fault, except the general charge of complication. This engine has 12 wheels of 4 feet in diameter, arranged in two groups, each group independent of the other, and driven by a pair of cylinders 18 inches in diameter with 24-inch stroke. Each bogie has a wheel-base of 8 feet 6 inches, and this length is practically the rigid wheel-base of the engine. The total wheel-base is 32 feet 6 inches, and this gives great steadiness to the engine, whilst, as will be seen, it does not interfere with its flexibility. The boiler is carried upon a cradle or carrier frame, which is in turn supported on the two bogie frames. The fuel and water are carried on the engine itself, the necessity for a tender is dispensed with, and the whole weight carried is made available for adhesion or grip on the rails.

The bogies are free to swivel on their pins, and each engine can radiate independently of the other; so whilst passing round even an S curve, each bogie can accommodate itself to the direction of the curvature without in any way interfering with the action of the other. The boiler has 2 barrels, each 13 feet long by 4 feet in diameter, these barrels springing from a central fire-box casing 10 feet 6 inches long. The barrels contain 352 tubes, 2 inches in diameter inside, and the boiler has altogether a total heating surface of 2,550 square feet. The grate surface is 32 square feet. Both the regulator and the reversing gear are arranged to be worked from either side. The tractive power of the engines, with a cylinder pressure of 100 pounds to the square inch, is equal to 33,400 pounds, or equivalent to drawing a gross load of 390 tons up a gradient of 1 in 25, at a speed of 10 miles an hour. The great points in favor of the double bogie engine are these: it admits of at least twice (and that an equal) subdivision of weight per wheel attainable with an ordinary engine. If such an extreme subdivision of weight be not desired, then it permits of the construction of a heavier and more powerful engine, with a given weight per wheel. So long as it has less than twice the number of wheels of an ordinary engine, it admits of shorter individual wheel-bases, and, indeed, this will generally hold good even where 12 or 16 wheels are employed.

One of these engines has been at work for some time past on the Neath and Brecon Railway, and Captain Tyler, who reported upon its working, described its motion over new and sharply-curved portions of the line as being so free from violent motion and oscillation, as to suggest to him the idea of "sailing." The South Western of Ireland is about to make trial of these engines, and another trial is to be given to one on the Central Pacific Railway. The engine, which has been built by William Mason, at Taunton, will shortly be put where its merits will be well tested, and its results brought home to us. At the western extremity of the Central Pacific the line ascends from Sacramento, at the sea level, to the summit tunnel in the Sierra Nevada, or Nevada Mountains, the ascent in a distance of 105 miles being no less than 7,042 feet, and the average inclination, therefore, 1 in 67 for the whole distance, while for 6 miles there are gradients of 1 in 45½, or 116 feet per mile.

By another arrangement of Mr. Fairlie's, that of hauling the trucks or cars from a centre draw-bar, each end working on a swivel, the largest of goods trains may be made to follow the curves and windings of a railway, without that risk of being pulled off the line which too frequently occurs in the case of long trains. This arrangement will be referred to in another article.

Meanwhile "Engineering" calls for other designs of 50-ton engines, and thinks there will be no difficulty in making a 6-coupled, 20-inch cylinder engine, with 2 feet stroke, 5 feet wheels, boiler 4 feet 9 inches diameter, 300 tubes 2 inches by 12 feet, 30 feet area of fire-grate, and 1,800 feet of heating surface; tractive force 16,000 pounds. Such an engine would have but 8 tons on a wheel, if the weights were properly distributed.

WILLIAM H. TALCOTT.—It is with regret that we record the death of this gentleman, which occurred on the 8th of December, at his residence in Jersey City. For many years Mr. Talcott has been known as among the most eminent of the Civil Engineers of this country. On all matters connected with hydraulics, his long and successful experience has given to his opinions especial weight and influence. It is not within the limits of this brief notice to enumerate the many public works with which he has been connected. From the very beginning of his professional life he has commanded the esteem of all who knew him; and his excellent judgment, his keen analytical powers, and unwavering probity, had placed him in the highest ranks in the profession. His name will always be remembered by those who knew him as that of an accomplished engineer, and a most estimable, upright Christian gentleman.

ALGERNON ROBERTS.—The untimely death of Mr. Algernon Roberts, of Messrs. A. & P. Roberts, Pencoyd Iron Works, Philadelphia, will be widely and sincerely mourned. He was one of our active, energetic, working engineers and managers, as well as a useful citizen and a genial friend.

MACHINE TOOLS.—One of the best features of modern mechanical engineering is the increased weight and better fitting of machine tools ; not simply because the work they turn out is better done, but because it is done more cheaply. For instance, a light planer can neither take a heavy cut nor a true one. When work leaves a tool, it should be finished —subsequent hand-scraping and draw-filing are neither beneficial nor economical. A planer can hardly be too heavy.

Another feature of modern practice is the use of special tools that can do one thing rapidly and truly, instead of convertible tools that can do anything. Versatility is not to be condemned, but in the extensive and regular reproduction of a given product, the sphere of the Jack-at-all-trades is limited.

Still another and a novel feature of modern tool-building is the devotion of the leading builders to various specialties —the 2 Philadelphia shops, for instance, that are known wherever good machine tools are appreciated. Although they are not relaxing their efforts in the production of miscellaneous tools, Bement & Dougherty make a specialty of Upright and Horizontal Boring Machines, Shaping Machines, Punching and Shearing Machines, Cotter Drills, and Steam Hammers. Their Boring Machine for the Boston Navy Yard, lately illustrated in various magazines, swings no less than 24 feet by the shifting of the uprights, and 12 feet ordinarily. Another machine from these patterns is constructing for the Washington Navy Yard. We notice at these works a Shaping Machine 20 feet long, with double travelling heads, for dressing out locomotive frames ; also a Pulley Turning Machine, to turn 2 at once, with round or straight faces. Among the Steam Hammers, the 250, 400, 600, and 1,000 pound sizes, for smith shops, appear to be thoroughly built and well adapted to miscellaneous work. The frame, slide, cylinder, and valve-seat or chest (rotary slide valve), are cast in 1 piece ; the anvil is independent. A considerable improvement in planers consists in casting side projections on the bed—widening it out—for straight vertical uprights, instead of bending in the uprights at the bottom ; this obviously stiffens the machine. Mr. Bement has overhauled the 40-inch lathe, making a very powerful, accurate, and highly adjustable machine. The live head is much lengthened, to give wider cones and heavier belts. A screw feed, for screw-cutting, is placed inside the bed, and is used for that purpose alone. It is reversed by clutches in the lathe head, instead of reversing overhead. Another rack feed is placed outside as usual. The lathe has an improved adjustable rest, supported on a heavy screw, to adjust the height of the tool ; also a facing-feed on the rest.

Among the specialties of William Sellers & Co. are Steam Hammers, in which their success has been remarkable, and is elsewhere referred to.

A NOVEL SQUEEZER.—In several of the iron mills where the Sellers hammer is employed, puddle balls are squeezed by being placed on the anvil and subjected to the powerful pressure of steam admitted above the piston. The squeezing saves much metal which would fly off under the *blow* of the hammer, or which would be crumbled off in the rotary squeezer. When the ball is compacted by pressure, it is patted and then hammered. This is the practice in making puddled steel.

The manufacture of the Morrison hammer, improved by Sellers, is a specialty of William Sellers & Co.'s business. The demand for Steam Hammers of all sizes, and especially of the smaller sizes for railroad and smith shops, is very largely increasing in this country, and this is a hopeful fact for better work and economical production.

THE SIEMENS' MARTEN PROCESS has been successfully started at the Trenton Iron Works, under the superintendence of Mr. Frederick J. Slade. Commissioned by several American steel and iron manufacturers to make a report on the state of the art in Europe, Mr. Slade devoted much time to these investigations, and especially to the study of the various new steel processes ; he also made a valuable contribution to the able report of Mr. A. S. Hewitt, United States Commissioner at the Paris Exposition. Under these auspices, we may look for the rapid development of this new and important manufacture.

SHIPS OF WAR.

THE MONITOR AND THE CASEMATE SYSTEMS COMPARED.

Abstract from various articles in "Engineering."

The advantages of the turret ship are these:

1. Having no masts, and having its guns and much of its armor further inboard, it rolls less than the broadside ship.
2. Its gun ports, being further inboard, would not roll under water, where those of a broadside ship, at the same angle of inclination, would do so.
3. For the same reason, the guns rise and fall through a less arc, and vertical aim can thus be better taken when firing in a sea way.
4. All its guns can be brought to bear on either beam, as well as a portion of them (where there are two or more turrets) on each beam.
5. The training of the guns is performed independently of the gunners, and their attention in loading, running out, aiming, and firing, is thus less interfered with than where the training is performed by hand and within the battery.
6. The guns can be trained nearly through the whole circle, upon an enemy manœuvring, and without turning the ship.
7. The turret ship can fight "end on," with the gun or guns of one turret, and nearly "end on" with the guns of all its turrets.

The advantages of the broadside system are:

1. They can carry masts and sails where the others, with their low freeboards, cannot safely do so. A ship with a high freeboard will roll through an angle at which a ship with a low freeboard would capsize, from the weight of water on one side of the deck. Thus the broadside ship may economize coal by setting sail where the turret ship has no sails.
2. Broadside ships in which men are exercised, messed, and berthed above the water line, are more habitable, healthful, and better lighted and ventilated than turret ships can be while cruising. Artificial ventilation may go far, but open-air exercise at sea is impossible.
3. The ship with a high freeboard carries its guns higher out of water.

It is only 8 years since 4½-inch plates would resist the best ordnance; now shot and shells are thrown by 50 to 100 pounds of powder through 5 and 6-inch plates, and the Whitworth flat-fronted projectiles penetrate even below water. And still heavier armor will soon be demanded to keep pace with artillery.

These are the respective advantages admitted, and the conditions required, but another important question is in dispute:

The partisans of turrets also claim that turret ships of a given displacement can carry thicker armor than broadsides; that, exposing a smaller surface to the enemy's fire, they are less likely to be hit, and that they can carry and work heavier guns. But when these alleged advantages are examined, they will be found to be to a great extent illusory.

It is easy to see that ships with 2 or more turrets—the Royal Sovereign has 5 and Admiral Halsted proposes 7—can carry very little more armor, with the ports the same height from the water, than broadside ships carrying the same number of guns. Although showing but little freeboard, the height of the armored side of the turret ship is much more than shows. The armor must go well down below water to provide for rise as the coal is burned out—a rise of 2 feet in a ship 300 by 50 feet for 500 tons of coal.

Supposing the *side* armor of the turret ship to be transferred bodily to the broadside ship. Then let us see how much more of the broadside ship the turrot armor would cover. Whatever the thickness and height of the turret, each one of them (25 to 26 feet diam.) presents 80 lineal feet for the protection of 2 guns, 160 feet (2 turrets) for 4 guns, and 240 feet (3 turrets) for 6 guns. A broadside ship 50 feet wide, with ports 20 feet apart, would enclose 4 guns at the ends and sides with 180 lineal feet of armor, and 6 guns with 220 feet. As the number of turrets is increased, so is the advantage of the casemated ship.

This comparison supposes the same height of sides; but even then the casemated ship is a high ship, and presents all the advantages of height above water, as far as the casemate extends.

The point, therefore, is not that one system presents more surface for protection than the other, but how far it is best to increase the height of armor in order to secure the advantage of a high side. The Koenig Wilhelm, clad with 2,800 tons, is regarded a good design. To add 7 feet to her height of armor, a foot thick all round, would increase the weight only some 900 tons. But it is the central battery only that requires protection for this additional height, and a battery of 100 by 50 feet, mounting 8 of the largest guns, increased 7 feet in height and a foot thick all round, would add but 450 tons weight of armor. The riddling of the unprotected high sides fore and aft the battery would be no serious matter.

Less surface presented to the enemy's fire is an advantage claimed for the turret system. But turrets always present half their diameter—a well-defined mark. Admiral Dahlgren reports that 8 monitors were hit 1,030 times while firing 3,587 shot. A broadside ship may be laid at a considerable angle of obliquity to the enemy's fire. The port holes exposed, and the use of port-stoppers, are the same for both systems.

Another claim for turrets is that only in them can the heaviest guns be worked. The same thing was said once of the 12½-ton gun, now worked in broadside. The Dunderberg works 18-ton guns in broadside. All that a turntable or a revolving turret can do is to train the gun; loading, elevation, running out and firing, have to be done by the same means in both cases. And in case of the revolving turret, some 125 tons of armor has to be revolved as well as the gun.

As to rolling: The monitors have their side armor built out over broad shelves projecting from the hull, and these act like bilge keels, or really, and more effectually, as side keels. These are equally applicable to broadside ships, and would lessen their rolling, while they would also lessen their speed, and we are not to forget that such a thing as a fast monitor never floated. Side projections, like the "guards" or extended sponsons of the American coasting steamers, or like even the paddle-boxes and sponsons of paddle steamers, greatly lessen rolling.

Again, although a war ship should be primarily perfect fighting machine, it may never have a chance to fight, but it must be the home of hundreds of officers and men for years.

The great advantage of the turret ship —facility of manœuvre—may be to a considerable extent obtained in the broadside ship by the use of twin screws.

But why not adopt Admiral Halsted's plan of mounting, say a couple of turrets on a broadside ship? The side plating of a 26 feet turret 7 feet high, and made of 15 inches solid iron, weighs 150 tons. With two of the heaviest guns now in use, with roof, central spindle revolving gear, and turret engines, the weight would be, say 300 tons. Two such turrets would thus weigh 600 tons, or about one-eighth of the displacement of a moderate-sized iron-clad—less than one-sixteenth that of the Northumberland. Yet consider for a moment what a ship Ericsson designed and built—the Dictator, to carry but 2 guns in a single 24 feet turret, 9 feet high, and 15 inches thick. That vessel is 314 feet long, 50 feet beam, draws 21 feet water, has a tonnage of 3,000, and, with no masts, a displacement of probably 5,000 tons. The engines, with 100-inch cylinders and 4 feet stroke, are to work up to 4,500 indicated horse power, and the boilers have far more grate area and heating surface than any vessel in the English navy. Now, when so much in the way of hull and engine power is provided in order to mount a single turret weighing in all, perhaps, 300 tons, why not carry the size of hull just far enough to secure the great advantages of the broadside system; and then, if thought best, retain the turret or turrets, placing them just above? Masts might or might not be retained; but such a ship would carry more gun power for its weight and cost, and be more powerful for destruction than any turret ship ever designed for the same speed and the same thickness of armor.

In conclusion, while admitting with respect to the strictly turret ships, all the advantages they really possess, it is impossible to deny that they should never, in the forms in which Ericsson and Coles have made them, enter into the navy *in any other capacity than as ships for coast and harbor defence.* If they are to have high freeboards, and to be masted and rigged, their turrets will be correspondingly high, and will thus increase the unsteadiness in a seaway. But thus improved, they would take a much better position in a comparison with broadside ships than they now do, and there would be good but not urgent reasons for their incorporation into the navy.

MARINE ENGINE IMPROVEMENT.

Compiled from "Engineering."

The marine engine in its present most advanced form is a splendid triumph of practical science and mechanical skill; but most middle-aged engineers can remember when, nearly 30 years ago, they thought the same of the clumsy contrivances, now long since obsolete, which then churned through the water, driving ugly hulls at 8 knots an hour. The simplest, lightest, and most economical marine engine of A. D. 1868, is still a complicated, heavy, costly affair, which, none can deny, needs a vast deal of improvement, if we can only find the means of improving it.

The theoretical advantages of high pressure steam, even up to 500 pounds or 1,000 pounds per square inch, and those of extended superheating, and of the utmost permissible degree of expansion, have been explained and insisted upon in innumerable pages of mechanical literature; and, still more ably and urgently, by the many apostles of an improved marine engine practice, who have passed or are now passing away. To what we may attain in the future, none can now pretend to say; but while it is undeniable that the principle of very high pressure superheated steam, with high piston speed and a high degree of expansion, is right, the cleverest engineers have only approached its advantages at a great distance in practice. No engineer need be told the reasons why, for they are known to all. At sea it would seem that, even with surface condensation, we are never to have pressures much above 50 pounds, although it is encouraging to hear so clever and so successful a marine engineer as Mr. John Elder, of Glasgow, who has succeeded with 50 pounds, expressing himself confident of attaining, with the same comparative success, a pressure very much greater yet. It is encouraging to find other engineers doing very well at a six-fold rate of expansion of 30 pounds superheated steam, in steam jacketted cylinders, and encouraging to know that Messrs. Penn's, Messrs. Maudslay's, and Messrs. Napier's very largest engines, are frequently run on trial, and for some hours together, at a piston speed of from 500 feet to 600 feet per minute.

The whole question of high pressure, say 50 pounds or 100 pounds at sea, turns upon that of surface condensation; and it is undeniable, that so far certain difficulties attending the use of surface condensers have rendered it necessary to keep to pressures at which sea water might, upon occasion, be employed in the same boilers, the vacuum being then maintained by means of an injection condenser, although the air-pumps, which are sufficiently large for a surface condenser, are altogether too small to pump out injection water. It is enough to say that whenever the long known difficulties—such as the furring of the condenser tubes, the accumulation of oil, acidulated or otherwise, in the boilers, or the corrosion of the boilers themselves—are once and finally overcome, there is nothing to prevent the regular use of 100 pound or 150 pound steam pressure at sea, any more than in locomotives upon land.

With injection condensers only a given amount of water is required for condensation, and to give more only needlessly lowers the temperature of the feed water, besides throwing additional work upon the air-pump, without obtaining any real improvement of the vacuum. But with a surface condenser the case is very different. With a moderate quantity of cooling water outside the tubes, a relatively large amount of tubular surface is necessary, inasmuch as the temperature of water rises so rapidly that it soon becomes nearly ineffective for the purposes of condensation, especially if the water be pumped from the Gulf Stream, the Red Sea, or any other warm source of supply. Some engineers maintain that it requires about as much cooling surface to get the heat out of the steam as it required of heating surface to get it in. The usual proportion of the former to the latter is about as 2 to 3 or 3 to 4. In any case the quantities to be dealt with are large. A pair of engines working to, say 2,000 indicated horse power, would, in moderately fair practice, require every hour the quantity of steam that would be evaporated from 900 cubic feet of water, or 15 cubic feet per minute. To condense this by injection, with the water at about 60°, would require 350 cubic feet, or 10 tons of water per minute. This would flow in from the sea; but its momentum being extinguished in the rose of the injection pipe, it would require to be lifted out again to the sea level, perhaps 10 feet or 15 feet, or even more; the work, exclusive of all losses, from friction, etc., thus amounting to from 7 to 11 or 12 horse power. Were the same quantity of water pumped through a surface condenser, there would be no loss of power (disregarding that from friction, bends, etc.) beyond that due to the head which would maintain the required rate of flow. If the 350 cubic feet per minute, or say 6 cubic feet per second, were to be passed through a net waterway of even 1 square foot, it would move at the rate of but 6 lineal feet per second, corresponding practically to a head of rather more than one foot. But much more than the ordinary amount of injection water is required with surface condensers. Yet on ship board, with the surface condenser 10 feet or 15 feet below the water line, 10 or 15 times the ordinary amount of injection water may be sent through without any real loss of power as compared with lifting out the injection water by the air-pump. In dealing with, say 3,500 cubic feet of water per minute (100 tons, or nearly 22,000 gallons of sea water), only centrifugal pumps would be reckoned admissible. No such large quantity is required in the case we have supposed, nor could any surface condenser adapted to engines of 2,000 indicated horse power well pass such a quantity unless the water ways between the tubes were needlessly large. Yet it is as well to remember the advantage which a large volume of condensing water affords, viz., that it renders a less extent of condensing surface necessary. The more water the less surface, the less total bulk of condenser, and the less cost.

Could marine engines be run twice as fast, they would require to be but half as heavy. Then why not run them faster? Because they would wear out two rapidly; the rubbing surfaces might heat, in spite of all lubrication—seize, and all would go to wreck together. This is exactly what would have been said, 20 years or so ago, of an attempt to run short stroke (4 feet) screw engines at 60 revolutions per minute, yet Penn's engines of that stroke, in the Bellerophon, have been run at 75 revolutions, and so far from breaking down are as good as new. Mr. Stirling's fine express locomotives, which we illustrated last week, running at 45 miles an hour, measure off 720 feet of piston per minute by the hour, and give no trouble. And were railways safe at still higher speeds, say 60 miles continuously, these engines would as easily (as they often now do for a few minutes) measure off from 960 feet to 1,000 feet per minute, by the hour together. Why should not marine engines do the same? Is it that there is not room for a 5-feet stroke, with a 10-feet connecting rod, and that 100 revolutions per minute are not required for the screw? If these are not the reasons what are they? It is certain that when we give up cast-iron pistons, of heaven knows how many tons' weight, when we employ hollow steel piston rods, when we abandon the ugly round connecting rods and adopt steel, channelled at the sides, thus I (or, if made to work through water, upon wood bearings as hereinafter suggested, they may be made of double edged sword section), when we adopt steel cross heads and bore out the axis of the crank pins and throws, we shall be enabled to run much quicker without jar or danger of heating. Lightness, good workmanship, and large bearing surfaces are all that is required to permit of the highest speeds.

Why should the stern bearing have the whole benefit of wood linings, the invention of which raised the screw engine and screw propeller from the depths of doubtful expediency to the summit of success? Silver linings—even they may be said to have been to the dark cloud which for so many years hung over the cause of screw propulsion. All the screw shaft bearings, including the thrust bearing, might be packed like the stern tube, with lignumvitæ, and they, with the shaft, might be enclosed in a plate iron trunk filled with water for 2 or 3 inches all around the shaft, and thus the bearings might go for months, if not for years, without being once looked at, and without the possibility of heating. And even the main bearings and eccentric hoops might be wood lined and worked in water.

As to the practice of various countries, "Engineering" concludes that the Paris exposition contained no better designed or better built marine engines than those by English builders, and instances an engine by Penn, weighing only 75 tons, but capable of 2,100 indicated horse power; also that some of the French designed engines of the Compagnie Générale Transatlantique, running to New York, had to be removed from the ships. It speaks well of the American beam engine for commercial purposes, on inland and outside waters. This type is of course unsuited to war service. It hopes that we Americans may long enjoy the monopoly of Mr. Isherwood's types of naval engines.

There is very little hope of improvement, this authority further concludes, from the use of the water jet propeller, or from the employment of liquid fuel at its present price.

SIEMENS' NEW PUDDLING PROCESS AND PLANT.

FACTS AND THEORIES.

Condensed from Mr. Siemens' paper before the British Association, the discussion, and the comments of the press.

Mr. Siemens set out with the statement that the present process of puddling was very defective, involving great loss of metal, waste of fuel, and of human labor, and an imperfect separation of the two hurtful ingredients, sulphur and phosphorus.

The molten pig iron in a puddling furnace is intimately mixed with the cinder formed in the furnace; the silicon is first separated from the iron; the carbon only leaves it during the later period of ebullition, and the sulphur and phosphorus separate last, while the metal is coming to nature. This much may be considered *proved* by analysis.

The old Theory of puddling adopted almost without investigation is plausible enough at first sight, and is thus stated: The pig iron when melted in the air furnace, being brought in contact with the air in its entire mass by mechanical stirring, undergoes an oxidizing process analogous to that which takes place in the Bessemer converter, the oxygen of the *air* taking away the silicon, carbon, and other impurities one after the other in proper succession. The iron ore used for felting (American, "fixing") combines with the silica formed by the oxidation of the silicon in the pig iron, and forms the puddling furnace cinder, which is charged moreover with different combinations of the phosphorus and sulphur originally contained in the pig iron.

Mr. Siemens' theory is that the pig iron, when molten in the puddling furnace and kept in contact with the fettling (which latter may be considered to consist of nothing but iron and oxygen) requires no oxygen from the air for being converted into wrought-iron. All that is required for its decarburization and desilicatization is an intimate contact of all the particles of iron with the liquid cinder formed from the fettling at a high temperature. The oxide of iron will then be decomposed by the silicon and by the carbon existing in the pig iron, and a large proportion of iron will in this manner be reduced from the ore.

Mr. Siemens goes a step further, and proves by the evidences of all the phenomena connected with the puddling process in an ordinary furnace, that even in presence of an oxidizing flame, the oxygen for decarburization is taken principally from the ore, and not from the atmosphere of the furnace.

Mr. Siemens' chemical reasoning is as follows: *Silicon.*—In forming (by the rabble) an intimate mechanical mixture between the fluid cast metal and the cinder, the silicon in the iron is brought into intimate contact with metallic oxide; being found afterwards in the form of silicic acid (combined with oxide of iron), it follows that it must have reduced its equivalent of iron from the cinder to the metallic state.

Carbon.—The disappearance of the carbon is accompanied by violent ebullition, and the appearance of carbonic oxide. The appearance of the process proves that the combination of the carbon and oxygen does not take place on the surface, but throughout the body of the iron. Mr. Siemens has also observed that no oxidation of fluid cast-steel melted on the open flame bed of a furnace, takes place as long as it contains a particle of carbon. Hence he concludes (by rather a long jump, we think) that the *oxidizing action* of the flame in a puddling furnace commences only after the malleable iron is formed, and hence the oxygen of the *atmosphere* of the furnace did not remove the carbon and silicon.

As to loss in the process, Mr. Siemens gives a calculation, the result of which is that assuming the pig to contain 3 per cent. of carbon and 3 per cent. of silicon, 10.5 per cent. of metallic iron should be added to the bath from removing the carbon, and 8.4 per cent. from removing the silicon, = 12.9 per cent. or 474 pounds of wrought-iron from a charge of 420 pounds of pig, whereas the actual yield is 370 pounds or 12 per cent. loss. He makes another calculation to show that 74 pounds of cinder are necessary to produce this 54 pounds of reduced iron, and says that this amount of cinder is considerably exceeded in practice. He quotes Dr. Percy as to the removal of phosphorus and sulphur (which are insufficient to affect the foregoing *quantitative* results, however they may affect *quality*) viz., that the crystals of metallic iron as they form throughout the boiling mass, exclude foreign substances just as water does in freezing—salt water forming ice that yields sweet water upon remelting.

Objections to the Theory.—As to the removal of carbon, by the cinder alone, rather than by the aid of the oxidizing flame, Mr. Siemens only presents a theory; if he has facts, he has unfortunately neglected to mention them; he does not say whether he used an oxidizing or a neutral flame in his practice. It is universally admitted that during the earlier period of the process, the presence of free oxygen is an advantage; it stimulates and facilitates the process, and entails no danger of oxidizing or burning the iron itself. The excellent results of the Richardson process of puddling—the tubular rabble to supply air, certainly show a decided action resulting from the *atmosphere* of the furnace.

As to the theory of removing silicon without the aid of an oxidizing flame, it is objected (in "Engineering") as follows:

The analyses of a puddling furnace charge in its various stages of progress show that the silicium is removed at the earliest stage, and that it disappears slowly and gradually during the process of melting and stirring, and before the commencement of the "boil." At that period the fettling is not *melted*, nor can it melt until it is converted into a silicate by the combination of the oxide of iron with the silica formed from the silicium in the bath. Silicium can take oxygen even from a neutral flame by decomposing the carbonic acid of the flame, but we have no evidence of its capability of reducing oxide of iron when in contact with it at a high temperature. On the contrary, it is known that a bath of pig iron when kept in contact at a high temperature with a slag of silicates, will reduce silicium from that slag at the expense of the carbon contained in the liquid pig iron. This property, too, is the cause of the difficulty which exists in the puddling process, and also in the Bessemer process to remove all silicon from the pig iron when the latter contains a very high percentage of that substance.

In reply to this Mr. Siemens states ("Engineering," October 2) the results of experiments showing that no silicon is taken up by the fluid cast metal in contact with silica or silicates. He charged 10 cwt. of Acadian pig metal and 1 cwt. broken glass upon the bed of a regenerative gas furnace (usually employed for melting steel upon the open hearth). The bed of this furnace was formed of pure silicious sand. The iron contained silicon 1.5 per cent., carbon 4 per cent. Analyses were made at the end of each hour, the silicon gradually decreasing. The reduction of the silicon might be accounted for by the presence of minute quantities of oxides of iron produced in melting the pig metal, which oxides were now increased by the addition of hematite ore in small doses. At the end of the fifth hour the samples taken from the fluid bath assumed a decidedly mild temper; when the addition of ore was stopped, and exactly 6 hours after being charged, the metal was tapped and run into ingots; it now contained silicon .046 per cent., carbon .25 per cent. Thus both the silicon and carbon had been almost entirely removed from the pig metal by mere contact with metallic oxide under a protecting glass covering. The quantity of red ore added to the bath amounted to 2 cwt., and the weight of metal tapped to 10 cwt. 5 pounds, being slightly in excess of the weight of pig metal charged.

We consider it probable that the advantage of Mr. Siemens' practice over the old practice is that it is performed in his gas furnaces in which the flame is absolutely under control, and that at the close of the process it can be made an absolutely neutral flame, instead of a partly or accidentally oxidizing flame to burn up the iron.

Mr. Siemens' new Practice is remarkable, however undeveloped or inadequately explained his theories may be.

During 18 months' working of a puddling furnace at the Bolton Steel and Iron Works, he has succeeded in making the yield of puddled iron in many cases fully equal to the weight of pig iron charged into the furnace. With regard to the economy of material, experience had proved that an ordinary furnace receiving charges of 484 pounds, yielding an average of 426 pounds, represents a loss of 12 per cent.; whereas his furnace received charges averaging 428 pounds, and yielded 413 pounds, representing a loss of 3.5 per cent. It was important to observe, moreover, that his furnace turned out 18 heats in 3 shifts, in 24 hours, instead of only 12 heats in 24 hours, which was the limit of production in the ordinary furnace. The quality of the iron produced from his furnace was also decidedly superior to that from the ordinary furnace. Beyond these considerations the consumption of fuel was also greatly in favor of his furnace, estimated at 25 per cent.

The consumption of the fettling was greater in the gas furnaces, and the superior yield was naturally attributed by forge managers to that cause. But the subsequent introduction of water bridges reduced the amount of fettling to an ordinary proportion, and experiments then proved that the use of his furnace gave an average yield of fully 12 per cent. above the ordinary furnace, while the iron was of better quality.

The Siemens' Furnace consists of a puddling chamber of very nearly the ordinary form, which, however, is heated by means of a regenerative gas furnace, the principle of which is well established. The advantages of this furnace for puddling are, that the heat can be raised to an almost unlimited degree; that the flame can be made at will oxidizing, neutral, or reducing, without interfering with the temperature; that in-draughts of air and cutting flames are avoided, and that the gas fuel is free from pyrites and other impurities which are carried into the puddling chamber from an ordinary grate. In this respect the new furnace presents the same advantages as puddling with charcoal.

The Siemens' furnace enables us to perform the operation of puddling with the following advantages: We commence the charge with a hot clear flame, which is kept up until the charge is quite liquid and raised to a very high temperature; at that moment we shut off the supply of gas altogether, drawing into the furnace nothing but pure atmospheric air, intensely heated by its passage through the regenerators. This is an "oxidizing flame *par excellence*," and its action upon the bath, when assisted by stirring the liquid mass with the rabble, must be rapid and effective. The next change must be effected when the liquid mass begins to rise in the furnace. The gas inlet must then be opened to its full width, and a flame overcharged with gas must be maintained to the end of the operation.

Cost of Furnaces.—It was stated that a pair of Siemens' furnaces cost about £450, which was rather more than the cost of a pair of ordinary ones; but the gas furnaces would make one-third more iron, which was equivalent to one-third of the cost, and the saving in iron and coal would more than pay the expense of the furnace in one year.

FARMING MACHINERY.

The improvement of the portable steam engine, no less than of the locomotive steam engine, to meet the demands of agriculture, is one of the most important problems of the day. There are already in England stationary engines of 100 indicated horse power, employed to drag gangs of ploughs. The application of steam to the other operations of agriculture is almost equally important. "Engineering" says: When all the advantages of steam are fully understood by farmers we may expect to see it applied on thousands of farms where, thus far, it has never been seen. It will be employed to mix clay and sandy soils, assimilating the texture of hill top lands to that of those in the valleys. It will be employed to pump farm and other sewage to where it ought to be pumped for irrigation, for sheep washing, for stone breaking, and in many other ways. The worthy steam farmer will be a sort of factory owner and engineer-in-chief, and many of his men will be mechanics, engine drivers, and stokers. The great farms will be almost in a single field, levelled where possible almost like a drawing table. The steam farming (not barnyard) engine can equally draw a plough, a cultivator, a barrow, a seed drill, or a drain plough, and it is not clear why it should not also draw a reaping or mowing machine, provided it was made sufficiently wide to render the application of steam profitable.

There are no less than 300 steam ploughs and cultivating sets now used in England. "Engineering" estimates that they have broken up and pulverized from once to 6 or 8 times, at least half a million acres (possibly much more, for it is exceedingly difficult to form any accurate estimate), and that in a manner never before known since ploughs were invented. There are now ploughing engines capable of exerting 100 indicated horse power, and capable of putting a draught of 3 or 4 tons upon an implement at a rate varying between 3 and 4 miles an hour. With such power any depth can be reached, and as the disintegrating power is, by a well-established mechanical law, as the square of the velocity, the soil is broken with 4 times the mechanical effect at 4 miles an hour, as in the case of a horse-drawn plough at two miles.

The committees of the Royal Agricultural Society on steam cultivation, published in 1867, after examining some 200 steam-tilled farms, report that "A culture deeper than it is possible for horses to effect, works a highly beneficial change in the texture of the soil, imparts additional efficiency to drainage works, augments the value of the manure applied, brings into operation certain latent properties of the soil, which much increases its fertility; it also fits land, formerly unfit, for the growth of turnips, allows of their being fed off by sheep, the operations of the field are economized, and the growth of all crops is stimulated." At the time of their report steam tillage was considerably cheaper than horse tillage. Now, the steam ploughing engine, rope, and other tackle, and the attached implements, have been very much improved, and the comparison would be still more in favor of steam.

But the greatest gain is in the improved crops due to thorough tillage, and this may amount to an extra quarter of wheat per acre, an extra 3 or 4 tons of turnips, or something equivalent, and in this way the average crop may be increased possibly to the extent of £10,000,000. There are many recorded instances of steam-ploughed fields yielding 2 or more quarters of wheat per acre more than fields of the same character of soil alongside, but cultivated by horses.

Although there is probably no more efficient and economical power than steam for large operations, the substitution for "one horse" operations of some safer and more cheaply managed power than steam, as at present generated and used, should merit the serious consideration of the profession.

The "American Artisan" suggests also the following important problems for agricultural engineers: The development of *compound machines* for preparing, by different changes of parts, the food for animals, whether of grain or stalk or root; for disintegrating and preparing refuse mineral and vegetable substances for fertilizing purposes; for cleaning fields from stones; for the rapid and efficient construction of drains, and for many other purposes which would be developed in time, but can hardly be now foreseen.

THE EVIL OF HASTY WRITING.—The "Round Table" commences a timely article on this subject with the remark that American journalists write *too much*, and states that the leader writers for the "London Times" furnish but one to three articles per week. Such articles are well digested, and worth more than all the pages written "against time." If hasty journalism is a defect in polite and political literature, how much graver the defect in scientific literature. Technical articles, of all others, should be highly matured; when loose and hasty, and especially when spun out to fill so much space, they are too long to be read—practitioners cannot afford the time—and they are likely to be incomplete and inconclusive.

But, notwithstanding the vast increase of trashy writing, secular and scientific, there is a growing taste for higher literary excellence in the one department, and a growing and acknowledged want of more learning as well as a better style in the other. This taste and want exhibit themselves in the form of *pay*. The better class of readers are making it an object for the better class of writers to contribute to periodical literature.

THE ATLANTIC WORKS, East Boston, are building several iron steamers and their engines, and employ 350 hands.

RUBBER TYRES FOR HIGHWAY LOCOMOTIVES.

Compiled from Accounts in the London and Edinburgh Press.

Mr. R. W. Thomson's road steamer, recently tried about Edinburgh, has given a new start to highway steam locomotion. The improvement consists in the use of thick tyres of India rubber, which are said to make all roads good roads, and thus to overcome the grand obstacle to this otherwise most useful and economical means of transportation.

After trying a smaller locomotive with success, Mr. Thomson built one of 8 tons weight, having a vertical boiler, and standing on two geared driving and two steering wheels.

The driving tyres are made of bands of vulcanized India rubber 15 inches wide and 5 inches thick. This soft and elastic substance carries the great weight of the locomotive, without injury, over newly broken road-ballast, broken flints, and all kinds of sharp things, without even leaving a mark on the India rubber. It does not sink into the road in the least degree. It passed over the stones lying on the surface, and even over potatoes and carrots, purposely laid in its path, without crushing them. It resembles in some degree the feet of an elephant. As remarked by Professor Archer, in his paper before the British Association, both the camel and elephant have very large soft cushions in hard hoofs, and no other animals can stand so much walking over hard roads.

The power required to propel the locomotive is very much less than what would be required if the tyres were hard and rigid. They do not crush nor sink into the roadway. The machine, as it were, floats along on the India rubber, and all the power used in crushing and grinding the stones under rigid tyres is entirely saved. It might at first sight be supposed that it would take a great deal of power to propel a heavy carriage on soft tyres; but if the tyres are elastic as well as soft, the power used in compressing them in front of the wheel is nearly all given back as the elastic medium expands behind the wheel. In fact, the India rubber tyres require scarcely any more power to propel them over soft, bad roads, or over loose gravel roads, than on the best paved streets.

On a soft grass field, in which an ordinary steam carriage would have sunk, the rubber tyres were run without even leaving a track. On a field which had just been covered with loose earth to the depth of 1 or 2 feet, they ran straight across and back, without difficulty, and compressed the earth so little that a walking stick could easily be pushed down in the track of the wheels.

When riding on the road steamer the feeling is like what would be experienced in driving over a smooth grass lawn. There is absolutely no jarring. Thus the machinery is spared the severe trials arising from the blows and jolts to which it is subjected when mounted on common wheels.

There is, incredible as it may appear, no indication of wear on the India rubber tyres. The original surface which the rubber had when it left the manufactory is still visible.

The tractive powers of the machine have surpassed all expectation. It was constructed to drag an omnibus, weighing, with its load of say 30 passengers, about 4 tons, on a level road, but its capacity is so greatly in excess of this task, that no load placed behind it has fully tested its power. On a road so slippery from frost that horses had the greatest difficulty in keeping on their legs, no difficulty was found in going over the glazed surface by the India rubber wheels, with a load of 13 tons (a large boiler on a truck) on an incline of 1 in 12.

On one occasion, the locomotive drew a coal train, in all 90 feet long, consisting of 4 wagons, weighing, loaded, 32 tons, 8 miles, over grades of 1 in 16.

The steering of the locomotive while hauling the coal train in the crowded streets of Edinburgh, and around sharp corners, was very successful. The line of streets through which it passed are always the most crowded in the city, but at the time the train passed through these thoroughfares there happened to be an unusually great current of traffic passing in a contrary direction to where some games were going on, which gave rise to a great stream of omnibuses, cabs, and conveyances of every description, in addition to a great crowd of pedestrians. Notwithstanding all these obstacles, aggravated by the streets being at some points under repair and closed for one-half of their width, no difficulty was experienced in steering clear of every impediment.

The extremely curious way in which the whole 4 wagons follow, snake like, in the track of the road steamer was clearly seen in passing out of North Bridge into Leith street. First, the road steamer had to turn to the right, and before the last wagon was round the corner to the right, the road steamer had already turned sharp to the left to go into Leith street—thus the train actually assumed the form of the letter S, every wagon going over the same ground as the road steamer with the most perfect accuracy. The very steep and crooked descent of Leith street, which has a gradient of probably 1 in 12, was managed with perfect ease. The final manœuvre was turning with the whole train out of a street 30 feet wide, into a lane 25 feet wide, up a steep incline. It passed in at the first trial, leaving so much space to spare that it was found, on afterwards measuring the wheel tracks, a width of 14 feet would have sufficed, though the breadth of the wagons is 7 feet.

As to usefulness for Army purposes, the "Railway News" remarks that a few of these engines working up the Col de Balaclava might have saved many lives in the Crimean winter of 1854, and the increased weight of siege ordnance would now give to an engine of this sort an importance which it could not then have possessed.

BOILER EXPLOSIONS—THE PROJECTILE THEORY.—This theory, started by Zerah Colburn, and advocated by D. K. Clark and others, meets with confirmation occasionally, by circumstances which no other well-defined theory will explain. For instance, in the explosion of a boiler at Wustewaldersdorf bleachery in Germany, a detailed account of which is translated from the Journal of the Association of German Engineers, for the "Iron Age" of October 1, a manhole plate was blown off from the boiler by reason of defective bolts; a sudden liberation of a great volume of steam ensued, and an explosion followed, tearing the seams and the solid plate in various places.

The German writer (Mr. Heaffman) observes that explosions generally occur after the sudden liberation of steam, and adduces experiments with glass boilers, viz:—Opening the safety valve slowly, let off the pressure without disturbing the water; opening it suddenly caused such a rapid generation of steam bubbles as to place it in violent commotion; the pressure fell 3 pounds, and immediately began to rise, when the boiler exploded and was shattered to powder. Boiling water was pumped into another boiler, and then air forced in until the boiler burst at the much higher pressure of 15 atmospheres, but with less report, and no shattering.

Mr. Heaffman attributes boiler explosions to electricity. But the theory is not well defined; it is only a guess. The projectile theory, however wrong farther knowledge may prove it, is at least well defined, and in these and many explosions there are all the conditions required to produce it, viz.: 1st, the sudden relief of pressure; 2d, the flashing of much water into steam, because at a reduced pressure it cannot exist, hot as it is, as water; 3d, the violent escape of this steam *carrying water with it;* 4th, the instantaneous blows of innumerable projectiles, large and small, of inelastic water upon the plates, shattering them irrespective of weak places, like the effects of cannon shot.

OLD AND NEW OBJECTS OF INVENTION.—The inventions of the last hundred years sometimes appear more grand and far reaching than any now being developed or demanded. But it must be remembered that the old inventors had a clear field. Everything was demanded and nothing was done. The steam engine, the cotton gin, the telegraph, smelting with pit coal, the hot blast, the rifled cannon, and all the other great inventions which have changed the whole aspect of life, were then unknown, and even the most imperfect development of them was more striking and revolutionary than the later and really more valuable refinements of the same inventions. And it does not follow that less useful work is wanted or likely to be done now. On the contrary, the improvements in steam power, for instance, likely to be developed during the next hundred years, will have a greater money value than all that has preceded—perfect as the steam engine is to-day. The old inventors were called upon to discover and open the doors of Nature's storehouse; the later inventors are called upon to bring out and set in order her wonderful secrets.

THIRTY-FEET FAN—IMPROVED CONSTRUCTION.—The centrifugal ventilating fan of M. Guibal, a Belgian engineer, has given good results after a prolonged trial in the mines of the continent, and is now introduced in England. It had previously been thought advantageous to allow the air to escape from the vanes of an exhausting fan as freely as possible—hence the univeral system of discharging round the whole circumference. After much careful study M. Guibal found it better to enclose his exhausting ventilator in a casing, allowing the escape of air at one point only; and it was equally in accordance with mathematical principles that the adoption of this casing was followed by the use of the peculiar chimney and sliding shutter, which are important features in this system.

The objections generally brought against centrifugal ventilators were—1st, the high speed, and consequently heavy wear and tear and liability to breakages; 2d, the comparatively small depression obtained, and the loss of useful effect by re-entries of air—rendered greater as the depression increased; 3d, the low percentage of useful effect, which even with the best known system abroad did not exceed 25 per cent.

The first objection has been overcome by increasing the diameter of the ventilators, originally about 6 feet, and making 400 or 500 revolutions per minute, to 30 feet; and they are intended to be 40 feet diameter, making 60 to 80 revolutions per minute. The second objection has been met by enclosing the ventilator in a casing, the only inlet of air being from the mine into the centre opening, and by the chimney, which is specially constructed on the expanding principle, and utilizes a certain amount of the power which would otherwise be carried away by the air entering its base at the high velocity which it has on leaving the blades of the fan. The result of experiment proves that a depression greater than that due to the velocity of the tip of the blade is obtained from the Guibal ventilator; this is due to the joint action of the "Evasée" chimney. In other centrifugal ventilators the depression obtained has been less than that due to the velocity. The third objection no longer holds when such a result as 60 per cent. to 70 per cent. of the steam power applied is utilized.

A fan 30 feet diameter by 10 feet wide is driven by a direct acting single engine with cylinder 24 inches diameter and 24 inches stroke. Fans of these dimensions are now giving at 60 revolutions per minute, a volume of 100,000 cubic feet per minute, with a depression of 2.5 inches.—*The Engineer.*

TIN-LINED LEAD PIPES.—Messrs. Broadnax & Co., in New York, and M. Hamon, in France, are manufacturing tin-lined pipe in large quantities, and, whilst the inner surface insures a perfect freedom from all the deleterious consequences arising from the use of water brought into contact with lead, the increased strength obtained from the superior tenacity of the tin enables the section to be reduced and the pipes to be manufactured at the same prices as ordinary lead tubing.

The operation in the American process consists in casting a conical ingot of pure tin, which is then bored out to fit a mandril, the size of which corresponds with the diameter of the pipe to be produced. This ingot, after being turned down in a lathe, placed in a refrigerator, and reduced to a temperature of 12°, is set upon the mandril, which is fitted into the ram of an hydraulic press, and exactly in the centre of a circular mould, into which lead is poured from adjoining furnaces, placed on each side of the hydraulic press. The mould is placed within a casing kept heated to a temperature of 267°, to prevent the lead from chilling and parting from the mould. As the tin has been reduced to a temperature of 12° above zero, it resists the superior heat of the melted lead, and only begins to change form as the former is hardening. A perfect junction between the two metals is thus effected without so much fusion of the tin as would destroy the continuity of the lining when the pipe is drawn out. When the ingot is cold the descending ram forces it through a die, forming a continuous pipe, with a tin lining, the thickness of which depends upon the size of the central ingot.

The process of M. Hamon closely resembles the American one just described. In preparing his ingot, the inventor casts an annular block of lead, and placing within the central space a hollow mandril of a less diameter than that of the hole in the ingot, fills it with tin, which he runs in from the bottom of the ingot, through the hollow mandril. The compressing process is in all practical details identical in each case, the main difference consisting in the addition of an auxiliary hydraulic cylinder for raising the cast-iron block containing the matrix, through which the pipe is forced.—*Engineering.*

UTILIZATION OF SEWAGE.—One of the greatest sources of waste in all American and most foreign cities, is the throwing away of the valuable fertilizing elements in the sewage. In China, that semi-barbaric, but exceedingly wise old land, the inhabitants of cities are obliged by law and custom to return all fecal matter to the country, where it may be restored to the soil, from which it came in the shape of vegetable and animal food. But the fluid matter is not available for manurial use, and the solid matter is difficult of separation, except through the tedious process of evaporation. A compound (of animal charcoal, blood, clay, alum, and some other things) has recently been patented in England, by which the solid material may be instantly precipitated in a coalescent mass, which is easily and quickly dried for manure. Some enterprising "contractor" could make any number of fortunes by getting hold of such an effective process. The refructification of soils is getting to be an important question along the Atlantic States.—*N. Y. Times.*

Another process, patented by Mr. C. G. Lenk, of Dresden, is a peculiar preparation of alum. In a recent experiment at Tottenham (Eng.), 26,000 gallons of sewage were discharged into the tank, and into this were gradually poured about 60 gallons of "Lenk's Patent Essence." At first the smell was most offensive, and nearly intolerable, but as the chemical preparation mixed with the liquid the odor perceptibly decreased. After some time a remarkable change was visible in the contents of the tank. The solid substances were precipitated to the bottom, the water on the surface became gradually clear, and at the end of an hour it was found to be not only transparent, but almost clear, by contrast with its condition when discharged from the sewer.—*Artisan.*

IMPROVED METHOD OF TESTING LARGE PIPES.—An apparatus for testing pipes and open-ended castings has been designed and recently patented by Mr. Henry Cochrane, of Middlesborough-on-Tees. In testing pipes by water pressure, the usual practice has been to close the ends by caps or bonnets, and then to force in water until the pipe was completely filled; but in the case of pipes of large size this system is open to two objections, the first being that, as the end caps are subjected to an enormous pressure, they require very strong, and consequently expensive fastenings to hold them securely; and the second being that a waste both of time and of water is occasioned by its being necessary to fill the entire capacity of the pipe. Mr. Cochrane overcomes these objections by placing a core, slightly less in diameter than the bore, within the pipe, and then pumping the water into the small annular space between this core and the pipe itself. By this arrangement, not only is the quantity of water which it is necessary to force in very greatly reduced, but the end caps are also relieved to a corresponding extent of the pressure to which, under the ordinary system, they would be subjected.

This apparatus is illustrated in "Engineering," October 2, 1868. The pipe is run over the core on a carriage, and the joints are stopped at both ends by screwing a cap upon one end.

WORKING THE 12-TON GUN.—Let us now stand for a short time upon the Seawall Battery at Shoeburyness, and watch the Royal Artillery officer and his "detachment" of 13 men work the 12-ton 9-inch gun. The object they have in view is to fire as rapidly as possible, consistently with taking a steady aim, at a target of only 5 feet square, moving across the range at 1,000 yards distance. By this means it may be ascertained how often the gun can be discharged at a vessel which the gunners are able to keep under fire while she passes along a distance of 750 yards, at 1,000 yards distance. The gun is mounted upon a wrought-iron carriage with slides, the whole being traversed upon racers. In 1 minute and 17 seconds after the first round the gun is again loaded, laid, and discharged. The third round, at the same interval of time, strikes the target, which is then moving at the rate of $3\frac{1}{2}$ miles an hour. In 4 minutes 52 seconds 5 rounds have been fired. The speed of the target is now increased from 7 to 8 miles an hour, and in 3 minutes 22 seconds 5 more rounds are expended, the fourth shot hitting the target. The general result is that the gunners would have placed all their ten 250-pound shells in a small gunboat, or even in a man-of-war's launch, in 8 minutes and 14 seconds.—"*Our Heavy Guns*," *in Macmillan's Magazine.*

RESISTANCE OF SHIPS DUE TO THEIR DEPTH — INFORMATION WANTED.—In a paper before the Institute of Naval Architects, Professor Rankine stated that every ship is probably accompanied by waves whose natural speed depends on the vertical depth to which she disturbs the water; and that consequently where the speed of the ship exceeds that natural speed, there is probably an additional term of resistance depending on such excess. In a later paper before the British Association, he gives some observations that prove the existence of waves whose speed of advance depends on the depth to which the vessel disturbs the water. The relation between those waves and the resistance, remains a subject for future investigation; but to facilitate that investigation, he calls for farther observations, such as the measurement of the angles of divergence of the wave ridges raised by various vessels at different speeds, and the determination of the figures of those ridges—also the mean depth of immersion as found by dividing the volume of displacement by the area of the plane of flotation, and that not only for the whole ship, but for her fore and after bodies separately.

FIRE PROTECTION AND WATER SUPPLY.—The system of Mr. B. Holly, of Lockport, in use in Auburn and other cities, consists in *forcing* water through the pipes of a city by powerful pumps, instead of drawing it from reservoirs, and also in the use of a "water telegraph" to indicate where and when the supply is wanted. The system is very fully discussed in the "Iron Age" of October 15.

THE ELECTRIC LIGHT—Berlioz electric light, used (and exhibited in New York) on the steamers of the General Transatlantic Company, is said to penetrate the densest fog and darkness, and to be of great value not only on deck, but in the streets of cities. This light is produced by the burning of carbon pencils in currents of electricity. The latter are furnished without the use of batteries by an apparatus consisting of 40 series of horse-shoe magnets set in a circular frame, within which is an axis bearing 64 reels of copper wire, and revolving before the magnets at the rate of 300 turns a minute. A double current of electricity is thus induced in the copper wires, the one direct as they approach the poles, the other reversed after they have passed them. No device for breaking the current is used, as it is found that, though the current is interrupted at each reversion, the light is not perceptibly affected unless the interruption exceeds one-twentieth of a second.

The magnetic apparatus is about 4 feet 6 inches square; it stands in the engine room of the *St. Laurent,* and is driven by a donkey engine of 1 or 2 horse-power. The electricity is conveyed to the lantern by wires. The cost of the light is about 12 cents an hour; the same amount of light by gas would cost 2 dollars. The light is displayed through a Foucault lens, which can be turned by hand in any direction, placed on the bridge above the deck.

Some interesting experiments have lately taken place in France on board the armor-clad ship "Heroine," and also on board the yacht "Prince Jerome," upon the use of the electric light for signalling purposes. The power of the light obtained was equal to 200 Carcel burners—the Carcel being equal to 8 candles; it therefore follows that the electric light possessed a brilliancy equal to 1,600 candles! In the direct line of the light it was stated as possible to read at the distance of 1,400 metres (1,531 yards) an ordinary newspaper. It was found that signalling by means of short and long flashes was the most easily to be carried out. The commissioners on the subject report, "The apparatus experimented upon shows a very powerful focus of light, perfectly suited to night signalling, or for throwing a light over a coast or a ship. It can be considered as a veritable floating light, and would then be most useful on board the flagship of a commander-in-chief." Of the peculiar value of this light and its intense illuminating power, it is stated that the yacht "Prince Jerome," fitted with it, was enabled to steam by night through the intricate navigation of the Bosphorus, when the yacht belonging to the Viceroy of Egypt was obliged to wait until daylight.

THE ST. LOUIS BRIDGE.

The arches of the bridge commenced by Captain Eads over the Mississippi at St. Louis, are thus commented upon in "Engineering."

In one respect the Mississippi bridge differs essentially from the ordinary run of arched bridges. Usually the spandril filling, even if arranged vertically only, possesses sufficient inherent stiffness, by virtue of the rigidity of its connections with the arched rib and horizontal girder, to assist materially in preventing any distortion of that member when under strain.

In the instance of the Mississippi bridge the spandril verticals are positively hinged, so that not the slightest incidental support is afforded by them to the arched rib, the stability of which is, consequently, since there is no horizontal girder, governed entirely by the self-contained diagonal bracing.

In fact, the essential part of the bridge is a curved rectangular beam, 8 feet by 44 feet, the former dimension being the vertical depth of the bracing, and the other one the distance apart of the face ribs, which are firmly tied together by horizontal bracing. There can be no question as to the lateral stability of the structure, but the depth of vertical bracing is so small in comparison to the span—8 feet to 515 feet—that it is absolutely necessary to consider the question of stability in that direction. Now, there must obviously be some limit below which the depth of the arched rib could not be reduced, even if the load were always uniformly distributed, and the mathematical position of the centre of pressure corresponded with the centre line of the rib. Thus, if the rib were but 6 inches deep, it could no more maintain its form, for an instant, than it would if built of ropes. Why a depth of 8 feet should be assumed, as it is in the calculations, to afford perfect immunity from all disturbing forces, we are at a loss to guess.

It appears to us that an arched rib, *per se*, is neither more nor less than a long column, and that it should, consequently, be treated as such. In a long column of uniform cross section, subject to two equal and opposite end forces acting at the centre of gravity of the cross section, the unit strain would, mathematically, be uniform throughout the entire column. Experiment proves, however, that in consequence of variations in the elasticity of the material the strain is in reality very unequally distributed over the cross sections; so much so, that in columns of certain length positive tension is induced by a compressive force. Now, how it is that in calculations concerning arched ribs, or, in other words, curved columns, the unit strain should be assumed uniform if the mathematical position of the centre of pressure at any point corresponds with that of the centre of gravity of the cross section at the same point, whilst in a straight column, under similar conditions, it is shown by experiment to differ so widely from it, is not to us apparent.

In the Mississippi bridge, the least dimension of the column is about $\frac{1}{64}$th of the length; but on account of the curvature of that member, it is in effect, to a certain extent, supported at the centre of its length; hence the equivalent ratio will be greater than the preceding fraction. We have not investigated the question minutely, but theory appears to indicate that the equivalent ratio would be $\frac{1}{64} \times \sqrt{2} = \frac{1}{45}$th of the length. If this be so, the elastic resistance of the steel to be employed in the bridge should have been deduced from that of a bar 45 inches long by 1 inch diameter, instead of from that of a bar 12 inches long only, as appears to have been done. In no instance do we remember the breaking strain of either a solid or hollow column being greater than $12\frac{1}{2}$ tons per square inch, or about one-half only the resistance a short column of the same material would offer. In a steel column the loss of resistance would probably be smaller in proportion, but it would unquestionably be far too serious in amount to be neglected in the computations of the strength of Mississippi bridge. We do not mean to assert that, even if the maximum strain were 25 per cent. greater than stated in the report, the bridge would not still be perfectly safe and serviceable; but, at the same time, we cannot account for the omission of this important element in calculations so refined as those instituted for the determination of the strains on that structure.

We cannot endorse all the statements advanced in the report as to the superior economy of employing iron or steel in compression. In fact, if the reasoning were sound, it would follow that the resistance of a cylindrical boiler flue to collapse would be greater than its resistance to a bursting pressure. It is well known, however, that even an approximation to this condition would, in practice, be attended with fatal results. The radius of the arched rib of the bridge we are considering is about 84 times its depth, so, within certain limits, it may be considered as placed under similar conditions to a cylindrical flue 7 feet diameter, constructed of $\frac{1}{2}$ inch steel plates, and subject to external pressure. The increased resistance which such a tube would offer, if properly stiffened by diaphragms, is well known to practical men, and precisely analogous support would be afforded to the arched rib if the spandrils were properly braced. Neglecting the element of the long column, the present arrangements would probably be the most economical; but if we include that in the consideration, it will be found that the increased strains from expansion, contraction, and deflection, due to the bracing of the sandrils, will be more than counterbalanced by the increased resistance the arched rib could offer to compressive strains, whilst, at the same time, the structure would be far less liable to vibration.

In illustrating the bridge, "Engineering" adds the following comments: We think a glance at the engravings will convince most English engineers that the question raised by us, as to the vertical *stiffness* of the bridge, was not without good reason. The mass of horizontal bracing is so considerable in comparison with that available for the prevention of distortion of the arched rib in a vertical plane, that at first sight it might be fairly concluded the greatest disturbing force was to act in a horizontal plane, whereas, as a matter of fact, we well know the force operating in that direction could never amount to a tithe of the vertical disturbing force induced by the passage of a heavy rolling load over the bridge. In fact, as designed, we think the St. Louis Bridge would hardly prove less lively than several existing suspension bridges.

CHEMICAL PREPARATION OF PAINT.

Building News.

It has been proved that the different paints employed in the decoration and preservation of timber, iron, and other constructive materials, are not simple mechanical mixtures of oil and mineral substances but true chemical compounds, and endowed with that closeness and intimacy of union that invariably attends similar combinations.

Recently, the French navy has ordered a new process of preparing paints, to be examined and reported upon by a special commission. By proceeding upon a chemical rather than a mechanical principle, it is stated that paints may be manufactured in any quantities in a very short space of time, and in a simple and economical manner, which would dispense with the greater portion of the heavy and expensive machinery at present required. Any one may satisfy himself of the fundamental principle upon which this new process is based. Make a small cake, of a very fluid constituency, with some water and a certain proportion of any of the following ingredients:—White zinc, minium, or lamp black. Add to this cake a quantity of linseed oil; if zinc be used the proportion of oil will be 32 parts to 100, if minium only $5\frac{1}{2}$, and for lampblack 110 parts will be required to 100 of that substance. The mixture should be well stirred, and after a few minutes the oil will be found to be chemically united with the mineral substance, and the water to have separated and floating upon the surface. This circumstance is manifestly due to the principle of "elective affinity," by virtue of which the mineral substance leaves the water and unites itself to the oil. The water having been drawn off, the cake is then consolidated and pressed something after the manner in which butter is made. The process can only be applied to certain mineral substances, among which are those principally used in the manufacture of oil paints.

The following is an outline of the proposed manufacture: The color or mineral substance after being finely powdered, is mixed with a large quantity of water, and then passed through a fine sieve or strainer of silk. The small residue can be repulverized in a mortar and ultimately utilized. The chief advantage claimed for the sieve is that it arrests many foreign substances. This is not completely accomplished by the cylinders used in the ordinary manufacture of paints. The foreign particles are cut up very small, but they are not crushed; after a short time blisters rise to the surface, occasioning much damage to the appearance of the work. The mixture, after passing through the strainer, is deposited in a tank, where it may remain, if desirable, for some months. After drawing-off the greater part of the water, the proper proportion of oil is added, and the mixture thoroughly agitated. The result is that the cake commences to form, and is precipitated to the bottom of the receptacle. It is then pressed to drive out the remainder of the water, and although a very little may permanently remain, yet it will not affect the value of the paint or injure its application.

The successive steps may be summed up as follows:—The action of the water facilitates the minute division of the mineral substance or coloring matter; that of the strainer arrests all impurities, while the extreme degree of division to which the mineral has been brought favors its ultimate combination and chemical union with the oil. By virtue of its specific gravity the newly formed pigment, insoluble in water, separates spontaneously.

THE PRODUCTION OF COTTON SEED OIL. The cotton seed in its ordinary condition weighs about 33 pounds per bushel, of which about one-half is oil-yielding kernel, and the rest husk or hull, the latter being covered with a short woolly coat of fibres or filaments. In the usual method of extracting the oil this hull is removed by machinery, and the oil is expressed from the kernels by subjecting the same to great pressure after being ground, about 60 gallons of oil being obtained from a ton of the hulled seed. The oil weighs about 8 pounds to the gallon, and may be used not only in the manufacture of soap, but for grinding paints, and, when of first quality and properly refined, as a table oil in the place of that obtained from olives. One reason why this branch of production has not thriven better may, perhaps, be found in the employment of costly machinery, which not only involves a large original outlay of capital, but necessitates the consumption of all the seed of a large neighborhood in order to keep the apparatus constantly, and thus profitably employed, while the most available method would appear to involve the use of cheap and easily-operated machinery. This would enable each proprietor to extract the oil from the seed at such times and under such circumstances as might be the most convenient, and to employ the cotton seed as manure to nearly the same extent as if the crude seed were buried in the earth, inasmuch as the oil is simply a hydro-carbon, worth comparatively little as a fertilizer, while the pomace or oil-cake, containing the mineral matter and substances capable of generating ammonia, could be used for manurial purposes.

The "American Artisan" calls the attention of inventors to this subject, and indicates the direction of improvement.

THE HYDRAULIC RAM.

Condensed from the American Artisan.

This machine, a well-known invention of Montgolfier, is used where a considerable flow of water with a moderate fall is available to raise a small portion of that flow to a height exceeding that of the fall.

A dam is erected across a stream so as to form a pond. From the lower part of the pond runs the supply-pipe, *near* the end of which is a waste-valve chamber, in the top of which is a conical waste valve which opens downwards, and which is large enough to pass the flow of the supply-pipe. At the end of the supply-pipe there is a conical valve opening upwards into an air-chamber, from the bottom of which the discharge-pipe rises. There is a valve on the top of this chamber which opens inwards, and admits a small quantity of air, to supply any loss caused by its diffusion in the water.

The following is the operation:—Suppose the waste valve to have been shut by pressure from within the supply-pipe, and to fall suddenly open, owing to the diminution of that pressure. The water then begins to flow from the reservoir through the supply-pipe and out at the waste valve, with a gradually increasing velocity. The weight and the load of the waste valve are so adjusted that the impulse of the current in the supply-pipe upon it with the maximum velocity, causes it suddenly to shut. Thus the flow of water through the supply-pipe would be instantly checked, if it were not for the instant opening of the valve at the *end* of the supply-pipe into the air-chamber, caused by the momentum of the water. When the pressure in the air-chamber is equal to the pressure in the supply-pipe, the valve between the two vessels is closed by gravity. During the flow of water into the air-chamber, and for a short time after the closing of the valve, the water is forced up the discharge-pipe by its momentum and by the pressure of air in the air-chamber. As soon as the pressure within the supply-pipe is reduced by the stoppage of its flow into the air-chamber, the waste valve opens and permits the escape of some of the water in the supply-pipe, and remains so until the current is again strong enough in the supply-pipe to close the waste valve and cause the water to force itself again into the air-chamber and through the discharge-pipe to the desired elevation.

The following proportions for hydraulic rams have been found to answer in practice:—Let h be the height above the pond to which a portion of the water is to be raised; H, the height of water in the pond above the outlet of the waste valve; L, the length of the supply-pipe, from the pond to the waste valve; D, its diameter; then $H=h\div 20$; $L=2.8\,H=0.14h$; $D=H\div 10=h\div 200$.

If Q be the whole supply of water in cubic feet per second, of which q is lifted to the height, h, above the pond, and $Q-q$ runs to waste at the depth, H, below the pond; then the efficiency of the ram has been found by experience to have the following average value:—$q\times h\div Q\times H=$ two-thirds nearly.

THE COMSTOCK lode in Nevada, valued now at $30,000,000, was sold by the discoverer for a horse.

ECONOMY OF CLOTHING BOILERS.

The following are the results of some experiments recently conducted at the Newport Ironworks, Middlesborough-on-Tees, to test the value of a good lagging—Jones's non-conducting cement. The boiler (vertical) was connected with a puddling furnace, and was not protected by a roof. It was worked at 50 pounds per square inch, and in the second experiment the whole of the shell, an area of about 280 square feet, was coated with the composition. During the experiments the weather was fine and warm, and the coal used, the iron produced, the time of the experiments, and all the other circumstances, were exactly similar in the two cases. A water meter was attached to the feed-pipe, and this showed the exact amount of water evaporated with and without the covering. The results were as follows:

Boiler not Covered.

Total water vaporized per meter, Monday to Saturday, 11,690 gallons.

Total time, 126 hours$=92\frac{3}{4}$ gallons$=$14.8 cubic feet per hour.

Boiler Covered.

Total water vaporized Monday to Saturday, 16,060 gallons.

Total time, 126 hours$=$127.5 gallons$=$20.4 cubic feet per hour$=$5.6 cubic feet per hour more than when the boiler was uncovered, a difference which plainly shows the immense loss of heat under the latter circumstances.

Experiments by Jacob Perkins long ago proved that in case of pipes filled with steam at 100 pound per square inch, 100 feet of surface exposed to the atmosphere are, under ordinary circumstances, sufficient to condense per hour the steam produced by the vaporization of a cubic foot of water.

Regarding this experiment "Engineering" says: "It will be seen that a square foot of ordinary heating surface has about one-fifth the heat-transmitting power of a square foot of freely exposed cooling surface; or supposing that in any given boiler the areas of heating and cooling surface are equal, the effect of the latter, if freely exposed, would be to reduce the evaporative efficiency of the boiler twenty per cent.

The exposed surface of a boiler, or its cooling surface, in no way differs from its heating surface; it is subject to the same laws, and, under similar circumstances, would produce similar effects. That a square foot of cooling surface withdraws from the contents of the boiler a less amount of heat than is imparted to them by an equal area of heating surface, is merely due to there being a less difference between the temperature of the atmosphere and that of the contents of the boiler, than there is between the latter and temperature of the gases in the flues. Other circumstances being equal, the transmitting power of any given area of boiler surface varies directly as the difference in the temperature on the two sides of it, any increase in this difference enabling the surface to transmit a proportionately increased amount of heat in a given time.

AN ACADEMY OF USEFUL SCIENCE.

In these days of national institutes and guilds of letters, it is a little singular that the practical sciences to which this age, and this country especially, owe their progress, should not be promoted and conserved by a national institution, not only respectable in names and talent, but powerful in wealth and numbers.

It should seem that we do not know the foundations of our physical progress. Were a philosopher of a previous century to revisit the modernized earth, to observe the revolution in every mode and attribute of life—the dissolving and recomposing of materials, the utilization of natural forces, the wonders of chemistry, the feats of engineering, the triumphs of machinery, the omnipresence of iron—were he to witness the grander features of modern science, the splendid works and enginery of transportation, transformation, and construction—the steamship, the locomotive, the telegraph, the iron bridge, the Bessemer process, the machinery of agriculture, of water supply, of illumination, of weaving, of printing, of compounding, eliminating, and shaping materials for infinite uses, of turning power into infinite channels, and the machinery that makes machinery—were he then to study the minuter and every-day relations of modern science to life, to rest and motion, to pleasure and work, to living and dying, to the exercise of every sense and the utilization of every perception, till the surging masses around him should seem so many modern Centaurs—half man, half engine—were he then to contemplate the vast and complex organization of this modern life, its political and social bearings, and the amelioration of human fibre and force by inanimate substance and power—were this ancient philosopher to witness these marvellous things, his first thought would be of the great conservatory of their laws and literature—the modern Athenæum in which they are developed and organized, and he would turn to look upon the crowning wonder of them all.

But he would look in vain. The greater wonder is that modern engineering, by which we mean, comprehensively, the science that utilizes the forces and materials of nature, has so far advanced without organized association of ideas. Each individual or school has to a great extent begun at the bottom of the ladder. The hard-earned knowledge of one has been of limited benefit to the others. One is groping to-day for what has been the settled practice of another for years. How much labor and money have been misapplied to the rediscovery of what was known, and only needed dissemination to have turned all this labor and money to a vaster unfolding of the unknown. How many seeds of splendid growth have brought forth common fruit because planted in uncultivated ground. How many mighty intellects and industries that could have reared the monuments of engineering to the skies, have passed away, leaving nothing but duplicates of their foundations.

But, upon closer inquiry, we find that the present progress has been chiefly the development of what previous schools had left unfinished, and that professional literature, institutions of learning, commissions, conservatories and museums, limited, local, and inadequate as they have been, were the real organism of progress. To supply in some degree the knowledge of current facts and practice, each enterprising individual and community of workers in engineering is sending its agents and commissions all over the world to find out the same thing, when the machinery of a common institution of engineering would send more and better knowledge not only to every scientist, but to every artisan. How vastly the safety and economy of railway transportation, for instance, would be enhanced by the dissemination of facts. Each one of the ten thousand engineers engaged in its construction, maintenance, and improvement, is toiling after what some hundreds of them know. And no hundred private authors, investigators, and experimenters, can meet the demand for this knowledge. They all tread over the same ground—the sum of their results is overwhelmed in the volume of their concurrent testimony, and no individual practitioner has time to digest and utilize it. If thorough, it is limited; if comprehensive, it is incomplete. Individual powers and fortunes are inadequate. Such investigations do not keep pace with improvement. The good practice of this year may be bad practice next year. The influence of knowledge thus acquired is local and limited. For these and other reasons it is not only a minimum result at a maximum labor and cost, but it is not faithfully and literally pursued nor intelligently followed.

A great central guild of engineering would, at the cost of the present independent investigations, present to the world the latest facts briefly, completely, and authoritatively. *Organized* research would not go round in a circle. Each of its Commissioners and Boards would have its right line of investigation, its compilers would separate the wheat from the chaff, and its publications would be the text-books of the profession. Then would the thinkers and workers in the great arts of engineering widen the range, elevate the character, and magnify the usefulness of its results, and not merely multiply the proofs that these heights are attainable. —*New York Times.*

MACHINE-MADE WATCHES.—The American Watch Company employs over 600 operatives, and has made nearly half a million watches. The success and economy of the manufacture lies in the fact that everything is done, as far as possible, by machinery.

WOOLLEN MANUFACTURE IN THE WEST. There are at the present more than 550 woollen mills in seven of the Western States, having altogether a capital of about $5,500,000. Western wool is beginning to be consumed at home.

MARINE BOILERS.

As compared with ordinary land boilers, the modern marine boiler is a light and compact, if not remarkably strong structure. But if we compare it with the locomotive boiler, it at once becomes a hulking, clumsy contrivance, to say the very best for it. Its weight, together with the water contained in it, will not fall much short of 5 cwt. for every cubic foot of water evaporated per hour, whereas one-third this weight answers in the locomotive.

When we consider how badly a thin and nearly square box—and the shells of nearly all marine boilers are little more than square boxes—is calculated to withstand internal pressure, we perceive the first element of weakness and consequent weight.

When, again, we perceive what a small proportion of tubular surface is presented in comparison with the extensive but indifferently effective vertical surfaces of half inch plates, and besides these the considerable surfaces under the ash-pit—generating little or no steam—there is nothing to wonder at as to weight. Water bottoms were absolutely necessary in wooden ships. Are they necessary or even desirable in iron ships? Locomotive boilers give a good rate of evaporation without them. Indeed, they have been tried on locomotives without the least advantage. And as for dividing the length of a boiler by means of 5, 6, or 7 water legs, into 4, 5, or 6 separate and distinct furnaces, what is the good of it? Look at the weight of plates, the stay bolts, the angle iron or flanging, the hand holes and the cleaning—and all for what? No doubt the "legs" unite the furnace crowns with the water bottom, and if not so secured the latter would endeavor, and no doubt successfully, to straighten itself out, like the hollow spring of a Bourdon gauge, into a vertical line with the back of the boiler. But if there was no water bottom there would be no straightening tendency of the kind; and even with a water bottom a water front, as in a locomotive firebox, would most effectually tie it to the crown plate, and, still more, very sensibly diminish the heat in the boiler room. As to a great flat crown plate 15 feet by 7 feet, more or less, it would be no more difficult to stay than the crown plates

5 feet by $4\frac{1}{2}$ feet of broad gauge locomotive fireboxes worked to 4 times the pressure per square inch. Nor would there be any difficulty in keeping the crown plate clean. The room now taken up by the "legs," 6 inches or more each, would be occupied by 2 additional vertical rows of tubes of hardly one-fourth the thickness, yet presenting much more effective surface. But if the furnaces must be separated like pigeon holes, or little chaples of ease, make the legs a foot through and perforate them with 4-inch tubes. These would give much additional surface of the most valuable kind, and they need not interfere with proper cleaning.

Marine boilers made with cast-iron ash-plates instead of water bottoms, and having no divisions between the furnaces, would weigh much less than at present, be much cheaper in first cost, and would present far more of the most effective heating surface, viz., of horizontal plate with the fire beneath it. The grate area would be enlarged, narrower air spaces would suffice, the draught would be better equalized, thinner fires maintained, and the "combustion chambers," or space for the mixture of the gases with air, would be very much increased.

All marine boiler tubes ought to taper, being smallest at the front or smoke-box door; but, unfortunately, if so made, they could not be set in the boiler, as there would be no room to enter them at or withdraw them from the rear end.

It would be worth while to consider also whether some form of furnace like the Wilson furnace could not be adopted in connection with marine boilers. In this case, with boilers fired athwart ship, they could be brought very much closer together, and the boilers on both sides fed simultaneously from a raised stage, on which the men could stand with comfort. If such a furnace were found to answer it would require feeding only through a hopper, and no slicing of the fire, or dragging the grate bars from beneath, inasmuch as there are no bars, and none but absolutely incombustible refuse.

The foregoing is from "Engineering." "The Engineer" objects to the locomotive boiler as difficult to place and work in a ship, and inconvenient to repair. It says: The more widely a boiler departs from the well-known return fire-tube or flue types, the more unsuitable has it proved itself for sea-going purposes, and therefore only return-tube and flue boilers are now used in the best practice. Nor is it difficult to determine why such is the case. Good tubular marine boilers evaporate as much water per pound of coal burned as any other boiler of similar dimensions that can be placed on board ship, while they last much longer and do their duty during their lifetime with more certainty than more complex arrangements. This may be all wrong in theory, but it *is* practice. The fact has been proved by over 20 years of experience. It is quite true that the marine boiler is not well calculated to carry high-pressure steam, but it is also true that boilers specially intended to carry high steam are unsuitable for use on board ship; nor has it been proved that peculiar advantages are to be derived from the use of very high pressures at sea.

"The Engineer" objects to large crown sheets as difficult to stay, unprecedented, and difficult to keep covered with water. To which "Engineering" responds: The celebrated American river steamer New World had 2 boilers and only 4 furnaces. With a working pressure of 45 pounds per square inch, their nearly flat crown plates were each 10 feet 6 inches long, thus presenting a nearly flat surface of $65\frac{5}{8}$ square feet, upon which the total steam pressure was nearly 200 tons, or 800 tons for the 4 furnaces. The evaporation, as given in Mr. Bartol's admirable work on marine boilers, was 7 pounds of water per pound of coal. The Isaac Newton had 2 boilers worked to 35 pounds pressure, the 4 furnace crowns being each 5 feet 9 inches wide and 9 feet 6 inches long, the length of grate being 7 feet. This vessel, with fan blast under the grate, burnt 50 pounds of anthracite per square foot per hour, with an evaporation of 6.2 pounds water to the pound of coal. The America, a steamer on the Delaware, has a single boiler with but 2 furnaces, each fired through 2 doors, and each crown plate of the enormous width of 7 feet 6 inches, and of the length (for a 7 feet grate bar) of 28 *feet*, and the rate of evaporation at 25 pounds pressure, is given by Mr. Bartol as 7.82 pounds water to the pound of coal, $29\frac{1}{2}$ pounds of coal being burnt per square foot of grate per hour. The 2 boilers of the Bay State, giving off steam of 25 pounds from sea water, and running daily for a considerable distance on the open Atlantic, have 4 furnaces with flat crowns 5 feet 6 inches wide, and 10 feet 4 inches long, the rate of evaporation being 5.82 pounds water to the pound of anthracite, and the combustion of the latter 38 pounds per square foot of grate per hour. Furnace crowns from 4 feet to 5 feet wide, and worked under pressures of from 15 pounds to 35 pounds, and under very rapid rates of combustion, are exceedingly common in American practice. In Weale's "Engineers' Pocket Book" for 1847–48 is a drawing of a very successful boiler, in which the crown plate of the furnace, nearly flat, is 11 feet 6 inches wide and 9 feet 6 inches long.

If we go from furnace crowns to grate areas we find, on looking at the boats of the western rivers of America, having their 6, 7, or 8 cylindrical boilers, externally fired, and loaded from 90 pounds to 150 pounds per square inch, single grate areas, 4 feet long, fore and aft, and 28 feet wide athwart ship, grates of 112 square feet area and fired with 2 tons of coal per hour. The writer once constructed a number of locomotive engines to burn anthracite coal, and the firebox entirely behind the wheels, and spanning a 6 feet gauge railway, was 7 feet 6 inches wide inside and 6 feet long in the direction of the tubes, thus presenting the enormous area of 45 square feet.

"Engineering" concludes that if the crown plate of a firebox were 10 miles square, there would be no difficulty whatever, as long as the boiler was properly supplied with water, in keeping it covered.

THE PRODUCTION OF OIL FROM COAL.

When shale or coal is submitted to distillatory treatment, the most volatile portions at first escape, leaving behind substances of continually decreasing volatility. As the operation proceeds, and on an increase of temperature, these are evolved in a gaseous form unchanged, or resolved into more volatile matters and residual products possessing a still greater fixity. These products vary in nature with the temperature to which the coal is exposed, and when it is distilled at a red heat it yields a large quantity of gaseous and but a small amount of liquid hydrocarbons. The proportion of liquid products is much greater at a lower temperature. Coal-tar obtained from the distillation of coal contains various basic substances, including ammonia, aniline, diculine, chromoline, pyridine, toluidine, and others possessing less importance. The acids include acetic and rosalic, among others, but the principal acid is carbolic or phenic.

The first products from the distillation of the tar are gases, then follow water and ammoniacal salts, with black oily matter. As the process continues, the proportion of watery products decreases and that of oil increases. The products become heavier than water when from 5 per cent. to 10 per cent. of the original quantity has passed over in the form of light oil. It must be remembered that as the light oils disappear from the still, the remaining substances become more fixed, and a higher temperature is required for heavier oils. As the products increase in density, creosote, or "dead oil," appears, naphthaline and other solid products then become abundant, and the oil assumes a viscid state; the final residue constitutes asphalte if the distillation be carried to a sufficient extent.

The light oils on rectification can be made to produce a still greater portion of heavy oil and crude naphtha. The heavy oils contain a number of hydrocarbons of high boiling point. If the crude naphtha be agitated, the supernatant liquid on rectification gives rise to highly rectified naphtha, containing at least 4 or 5 oils, with specific gravities ranging from .860 to .890, and with boiling points from 149° to 392° Fahr. The watery liquids produced in the condenser during the manufacture of gas are employed for the production of sulphate and chloride of ammonium by a process of concentrating, crystallizing, and sublimating the crystals.

At the Ardsley Works, the retorts are 50 in number, and of an oval form. They are arranged in 2 sets of 25 each. Each retort weighs about 2½ or 3 tons, and contains from 10 to 15 cwt. of coal. The crude oil from the retorts is pumped into the stills, 3 in number, each having a capacity of 1,500 gallons. A small fire is placed under the stills, but the chief part of the heat is communicated to the body of the oil by means of superheated steam in a wrought-iron pipe entering the top of the still and carried nearly to the bottom, where it forms a coil, which is perforated with small holes; steam is thus blown into the body of the oil. The amount of water introduced into the oil by the condensation of the steam is inconsiderable, and is readily separated. The distilled oil is collected in a tank from a coil laid in a cistern of cold water in the usual way.—*Mechanics' Magazine.*

ANCIENT ROMAN MASONRY AND MORTAR.

A paper on this subject, by Mr. Spiller, F. C. S., read before the last meeting of the British Association, says: A more than antiquarian interest attaches to the remains of Roman constructive works in England, as they appear to have withstood the ravages of time better than the Norman and mediæval monuments of a later period. The walls of the Castrum of Burgh, Suffolk, are of rubble masonry, 6 feet thick, faced with flints and layers of red tiles. The stones are large, and the mortar reddened by pounded brick. Although the structure is estimated to be 1,500 years old, one wall, with a gate in the centre, is still perfect throughout its length—650 feet. The following chemical points are discussed:

1st. To what extent the hydrate of lime becomes recarbonated by exposure to air?

2d. What is the physical candition of the carbonate so produced? and

3d. Whether in this long interval the silica and lime can directly unite with each other?

Different views on this subject have been advanced, the prevailing opinion undoubtedly being that the lime never becomes thoroughly recarbonated, but stops short at a point when a definite combination of hydrate and carbonate of lime is formed; and, secondly, that lime is endowed with the power of attacking sand and other forms of insoluble silica by long contact at the common temperature.

The conclusions of the author are, that the lime and carbonic acid are invariably united in monatomic proportions, as in the original limestone rock; and that there is no evidence of the hydrate of lime having at any time exerted a power of corroding the surfaces of sand, flint, pebbles, or even of burned clay, with which it must have been for lengthened periods in contact. Further, that the water originally combined with the lime has been entirely eliminated during this process of recarbonation; and, this stage passed, the amorphous carbonate of lime seems to have become gradually transformed by the joint agency of water and carbonic acid into more or less perfectly crystallized deposits or concretions, by virtue of which its binding properties must have been very considerably augmented.

Analysis of the Roman mortar and of the red bricks, or tiles, gave the following results:

Roman Mortar from S. E. Tower, Burgh.

	I.
Sand	54.50
Soluble silica	0.40
Red brick with some unburnt clay	18.00
Carbonate of lime	25.75*
Sulphate of lime	0.15
Carbonate of magnesia	0.08
Chloride of sodium	0.05
Magnetic oxide of iron	traces
Wood charcoal	traces
Water, chiefly hygroscopic	0.92
	99.85

Samples of Burgh Mortar.

	II.	III.	IV.
Sand and brick, with a little unburnt clay	72.3	71.4	67.0
Carbonate of lime, etc. (by difference)	27.7	28.6	33.0

Samples II. and III. taken from the south wall. Specimen IV. from the north wall.

Red Brick or Tile from S. E. Tower, Burgh.

Silica	72.7
Alumina	14.0
Peroxide of iron	10.0
Lime	2.1
Magnesia	traces
Oxide of manganese	traces
Loss	1.2
	100.0

STEEL-HEADED RAILS.—The Montour Iron Works at Danville, and Cooper and Hewitt at Trenton, are producing puddled steel-headed rails of good quality, and filling large orders.

* Found, lime 14.5, carbonic acid 11.25 per cent.

IRON STEAMSHIPS AND HOW TO BUILD THEM.

The days of wooden hulls and sailing vessels are numbered. The iron hull, properly constructed, outlasts, perhaps, half a dozen wooden hulls—the first iron ships, if not running to-day, were only broken up because they were too old-fashioned. The iron hull greatly increases strength, durability, carrying room, and capacity for fine lines, heavy enginery, and consequent high speed, with a given displacement. And regularity of arrival and departure, and the consequent economical regulation of all associated business transactions, have rendered steamships preferable to sailing ships, even to carry coal, which of all freights can afford to wait. Wind costs nothing, but time is money, and steam and time, like power and heat, are convertible terms. Few if any sailing or wooden vessels are building in Great Britain, and our leading constructors and merchants admit that iron steamship building must be the leading feature in the resurrection of our ocean supremacy.

The history of iron ship-building in Great Britain is full of instruction, and if our builders are wise, they will profit, not only by the mistakes, but by the talent and experience of European constructors. The early iron ships were well built, of plentiful and good material, but not with the greatest economy of it, and many of them are running to-day. Their wonderful endurance in sea-ways and on lea-shores is proverbial. Afterwards the business was overdone, just as locomotive building was in this country a few years ago, and as a result cheap and bad work; *Royal Charters* and *Connaughts* were put afloat to the peril of money as well as life. And at last science came to the rescue; less material is so placed as to insure greater strength, and people are beginning to pay good prices and to get good work out of good ships. The successful transatlantic companies do not go to second-class builders; they cannot afford to run cheap ships.

There are no second-class iron ship-builders in this country yet, and this is the promising feature of the enterprise. If our builders never turn out bad work, they and our merchants and the public will be vastly the gainers in the end. We can better postpone iron ship-building another decade than to lower the standard of American work.

And still greater reforms and improvements must be introduced. Thick plates and costly material, piled into places where they cannot work, must be abandoned. A rib placed where it can receive a maximum strain, costs no more than a rib placed where it is merely dead weight. A ship is primarily a beam. As a beam it receives every strain of the sea. Now, a bridge or any girder made up of a thin, light web, running from end to end, and great vertical parts without longitudinal connection, would hardly sustain itself. Yet a ship so constructed is expected to hold up the enormous weight of its unsupported ends every time they overhang the trough of the sea, and of its partially supported middle every time the ends are buried in the waves—a constant and powerful vertical and lateral strain upon every joint in the hull. The great strain on a ship is the perpetual pulling apart and shutting together of its bottom and deck in a longitudinal direction, and yet the greater number of iron ships have been built without sufficiently strong bottoms and without any top strength except their sides. Many ships have first broken apart at the top sides and then gone to pieces. Heavy, continuous iron decks along the sides have partially remedied this evil. But the grand reform in this direction is to make the frames, the *ribs* of the vessel, longitudinal instead of vertical. Now, they are chiefly studs upon which to nail the siding. By making them continuous from end to end, they perform every present function and add their enormous strength *in the direction of the greatest strain.* Some genius has objected to the longitudinal rib system because the ribs of fishes are vertical. But while the rolling top of the sea forms a constantly varying support for a ship, a fish swims in a uniform medium that would not bend a reed—not on the water, but under it—and it has been observed that ships built like fishes have a tendency to do the same thing.

If our iron ship-builders will place our superior iron only where it can work, so as to use less of it, they can at once and successfully compete with foreign builders in cost and quality, and so revive not only our workshops, but our merchant marine.—*New York Times.*

PRESERVING TIMBER.

The chief cause of the decay of timber lies in the fermentation or decomposition of the albuminous matter contained therein. This matter may be neutralized by chemical agencies, as by the well-known processes of Burnettizing, Creosoting, etc., or it may be coagulated and destroyed by heat, which also hardens the wood. The charring plan is, however, for obvious reasons inapplicable for general use. The albumen may also be expelled or nullified by thoroughly steaming the wood.

Says the "American Artisan": Where time can be allowed therefor, it will be found quite efficacious, and more economical, to saw the timber to sizes but little larger than those to which it is to be wrought, and then place it, for a few weeks or months, in a stream or pond, where the water will gradually dissolve and wash away the nitrogenized or albuminous substances. The wood must then be thoroughly dried slowly, as a too speedy expulsion of the moisture would be apt to induce checking; the ordinary method of piling the stuff is, however, sufficient, the pieces of timber being kept at slight distances from each by suitable intervening strips, and the whole, when possible, protected from the sun and from strong currents of air. Inasmuch as the moisture will pass off less readily as the pores at the surface of the wood become closed by drying, it is well to complete the seasoning system by a process of kiln-drying, which at this stage will not check the timber.

The method of creosoting timber, which was lately invented by Professor Seeley, of New York, consists of subjecting the wood to be saturated to a temperature of about 230°, while in a bath of creosote oil, for a sufficient time to expel all the moisture, and to coagulate the albuminous matters of the wood. When the pores are thus freed from the water, and contain only steam, a cold bath is substituted, so far as to reduce the temperature from 230° to 65° or 70°, by means of which change the steam in the pores of the wood is condensed, and a vacuum formed, into which the oil is forced by an atmospheric pressure.

The process, says the "Detroit Post," has all the advantages of the method which has been in use in England and on the Continent for many years (and experience has demostrated that creosoted timber is still sound after being in use more than 22 years), and is much more simple in its application, and consequently more economical and expeditious than the English process.

Among the advantages claimed is the very important one that green wood can be treated as successfully as dry. The apparatus for creosoting, which has already been shipped to the Flats, and is now being erected on the dikes of the canal, was built in this city, and consists of a cylinder 45 feet long and 8 feet diameter, with a steam coil in the bottom and a movable head. The cylinder rests upon substantial timbers, and when the head is removed the lumber is run into the tank upon trucks. In addition, there are 2 receiving tanks for oil, each 15 feet in diameter and 6 feet high, with engine and boiler, connecting pipe, pumps, etc.

It is expected that this process will be applied to the timber to be used in the government works about to be begun at Toledo. Mr. Pelton has also similar works now in successful operation at Chicago for treating railroad ties and dock timber.

The Chicago, Burlington, and Quincy Railroad Company are preserving all their sleepers. They have at the Aurora shops a tank of boiler iron 10 feet square and 7 feet deep. This is filled with ties and closed with a tight cover, when carbolic acid sufficient to cover them is let in, and raised to a temperature of 245° by the application of steam. Here the ties remain for 30 hours, at the close of which they are thoroughly permeated with the carbolic acid and become as black as charcoal.

As to the duration of creosoted sleepers, the "Railway News" says: According to experiments and accurate records kept in Germany, sleepers of uncreosoted or natural oak last, upon the average, 15 years. By creosoting or impregnating them with other preserving substances, they endure for upwards of 22 years. From the same authority we learn that creosoted fir sleepers have a duration of about 13 years, while pine and beech will not last longer than 9. The lighter description of traffic prevailing over the German lines, which have furnished the above results, is the real cause of the sleepers lasting so long. It is needless to remark that upon our heavily worked railways they do not enjoy so long a life, but succumb, in the majority of instances, to wear and tear in about half the time, and in many instances much sooner.

LIQUID FUEL—DORSETT'S SYSTEM.

RESULT OF EXPERIMENTS ON THE STEAMER RETRIEVER.

This system of burning liquid fuel under boilers, says the "Mechanics' Magazine," is extremely simple in its details; it consists of a generator, which is nothing more than a small portable vertical boiler, in which the creosote is vaporized under a pressure of from 35 pounds to 40 pounds (932°), the vapor being led through a pipe to the furnace of the steam boiler, under which it is burned in jets.

In the trial of this system on the steamer Retriever, of 90 nominal horse power and 500 tons burden, there were 2 of these generators, which were placed on the deck of the vessel against the boiler casing, the pipes being carried down from them to the boiler furnaces. The creosote is pumped into the generator, a shovelful of live coal is placed under it, and as soon as the vapor begins to distil over, it passes down a pipe into the furnace of the generator. There it issues from perforations in the pipe, and continues the duty commenced by the coal, and supplies the vapor to the boiler furnace.

The adaptation of the coal furnace of the Retriever to the purpose of burning liquid fuel was effected by removing the furnace bars and filling the ash-pit with two layers of perforated fire-bricks. The apparatus is more fully described in "Engineering" as follows: About 3 inches above the floor of each ash-pit is placed an iron plate, which extends the full length of the furnace, and is curved slightly upwards at the inner end, where it projects into the return box. At a distance of 3 inches above this plate is placed another shorter plate, this latter being perforated, and being covered with a layer of fire-bricks placed loosely on it. At the front end the space between the 2 plates is closed by perforated bricks, which admit a certain supply of air, and at the inner end it is blocked up altogether, so that any air entering through the perforated bricks just mentioned can only find its way into the furnace by rising through the perforations in the upper plate and through the interstices of the layer of bricks by which that plate is covered. The air passing in between the lower plate and the bottom of the ash-pit is conducted right through into the return box for the supply of the jets of vapor placed there, and the amount thus admitted is regulated by closing the front of the opening to a greater or less extent.

The branch pipe led into each furnace makes a single long convolution just above the layer of bricks already mentioned, and then returns to the front of the boiler, and is connected to another pipe which is provided to discharge any creosote, etc., which may condense in the pipes. Each pipe is provided with independent inlet and discharge cocks. Each of the pipes in the furnace is pierced with 4 holes rather more than $\frac{1}{16}$ inch in diameter, and the pipe carried transversely through the return box is pierced with 8 similar holes, these being placed, 2 opposite the end of each furnace, and 1 over each of the water bridges between the furnaces. The boiler is thus heated by 20 jets altogether, of which the set of 8 in the return box, or each set of 4 in the furnaces, can be worked independently. When the vapor is first turned into the pipes a portion of it is of course condensed, and this portion is blown off through the discharge pipe already mentioned. As soon as the pipes become heated the discharge cock is closed, and it is afterwards only opened occasionally to get rid of any liquid that may have accumulated in the pipes.

During the preliminary trip of the vessel, the steam was maintained at the usual working pressure, and it was stated that the vessel made 1 knot more per hour than she had been accustomed to make with coal. The consumption of creosote was between 35 and 40 gallons per hour, as against 8 cwt. of coal, and considering that the present price of creosote is only about 1 penny per gallon, a great saving was apparent.

The official report of Dr. Paul on a subsequent trial trip, contains the following facts: The duration of the trip was 4 hours and 35 minutes. The oil weighed 10.5 pounds per gallon; the weight of oil consumed was 2,416.4 pounds or 1.078 tons, the average rate being 527.6 pounds (= 50.25 gallons) per hour. Experiments on the rate of vaporization of water showed the rate to be 12.3 pounds heated from 60°, and converted into steam at 212° per pound of oil. During the trial very little smoke was produced, and during great part of the time none at all. The temperature of the furnace gas passing into the funnel ranged from 250° to 350° C. (= 482° to 662° Fahr.), or, on the average, about 572° Fahr., and, as the external atmospheric temperature was about 50° Fahr., the waste of heat in the discharge gases corresponded to an increase of temperature to 522° Fahr. above that of the air consumed in feeding the furnaces.

For the purpose of arriving at some approximative estimate of the extent to which the result obtained in this practical trial corresponds with the actual evaporative power of the material used, Dr. Paul calculated theoretically the amount of heat it is capable of generating, and the maximum effect to be expected from its application under the ordinary conditions obtaining in practice. So far as the chemical nature of dead oil is known, it is a mixture of several substances—such as phenol and cressol, which contain, besides carbon and hydrogen, some oxygen, together with a variety of hydrocarbons, such as naphthaline, xylol, cumol, cymol, and perhaps others. According to the chemical composition of these substances, and on the assumption that the combustible carbon and hydrogen they contain will generate when burnt with just sufficient air for perfect combustion, quantities of heat sufficient for converting respectively 11.359 pounds, and 41.895 pounds of water at 60° into steam at 212° Fahr. for each pound of carbon or hydrogen burnt, when allowance is made for the heat rendered latent by the vaporization of the water resulting from the combustion of the hydrogen, and for the waste of heat due to the furnace gas being discharged at a temperature of 600° Fahr. above that of the air supplied to the furnace for combustion, the theoretical evaporative powers of these substances, and the evaporative duty they are capable of effecting will be as follows for 1 pound weight of each:

	Evaporative power. lb. of water at 212° Fahr.	*Evaporative duty. lb. of water at 60° Fahr.*
Phenol	12.2437	10.5025
Cressol	13.0096	11.1632
Naphthaline	15.4635	13.2675
Xylol	16.5866	14.2415
Cumol	16.7838	14.4126
Cymol	16.9422	14.5500

The result thus arrived at on theoretical grounds presents a very striking approximation to that obtained on the practical trial on board the Retriever on October 23d, viz., 12.356 pounds for the evaporative duty, which is only .667 less than the maximum duty indicated by calculation. If it be correct to regard the composition of dead oil as represented above, this approximation between theoretical and practical results would indicate that the application of liquid fuel, according to Messrs. Dorsett and Blythe's system, insures not only a very perfect combustion of the oil, but also a very full utilization of the heat generated. The very small amount of smoke produced during the trial would involve some waste of heat, and would to some extent account for the difference between the two results; but it must be remembered that in the trial the average temperature of the furnace gas discharged into the funnel was only 572° Fahr., or 522° Fahr. above that of the air supply, while in the calculated result it is taken as being 600° Fahr. above the air supply; so that in the practical trial there was a more efficient and economical application of the heat generated than has been assumed in the calculation.

A still further economy of the heat generated might be effected by heating the air supplied to the furnaces by the waste heat passing away into the funnel, and it is probable that in this way the combustion might be regulated and rendered so perfect that there would not be any waste of heat arising from smoke. These considerations lead to and justify the presumption that when the various appliances for burning liquid fuel according to this system shall have been more thoroughly perfected and adapted to the conditions and requirements of steam navigation, an evaporative duty of 13 pounds per pound of oil burnt may be realized.

But having regard only to the result actually obtained at present, it will be seen that the evaporative duty realized in the trial is about 100 per cent. greater than that ordinarily obtained with an equal weight of coal in steam vessels—that is to say, a duty of about 7 pounds per pound of coal consumed. Therefore the weight of oil required to fuel a vessel would be only one-half that required of coal, or the weight of fuel to be carried would be only one-half as much as when coal is used. Then taking the ton of coal as stowed on board a vessel to occupy 43 cubic feet and the ton of oil as occupying 34 cubic feet, the quantity of oil equivalent to 1 ton of coal, would occupy only 17 cubic feet, so that the saving in stowage space would amount to 60.4 per cent. of the space required for coal.

CONSTRUCTION OF LOCOMOTIVES IN GERMANY.

BY M. S. STUTZ, C. E.

Translated from "*Annales du Génie Civil.*"

From the date of the Universal Exhibition of 1855, where for the first time they saw German locomotives, the attention of French engineers has been awakened and drawn towards a particular class of these engines. Since then the Germans have made further progress, as the Exhibition of 1867 has proved, in showing us a series of locomotives, the elegance and finish of which excited general remark. The general design of these machines has been sufficiently described by Mons. Jules Gaudry, engineer of the Eastern Railway, in the *Studies in the Exhibition of* 1867, where our readers can find full accounts of them. What we now propose to consider are certain new dispositions and details, which constitute a real progress; and in this we shall avail ourselves of a report read by Mons. De Leoben, in a reunion of the engineers of the district of Stettin.

The German engineers have labored to reduce the construction of locomotives to the utmost simplicity, especially the mechanism for the distribution of steam. From this has resulted a general disuse of separate expansion valves. On the other side, there has been a disposition to make new trials of balanced valves; the results of which appear very satisfactory.

The application of the simple link of Stephenson has become general; excepting some cases in which Allan's straight link is used. But still the valve gear of Heusinger de Waldegg is often used. In this the link is worked on a fixed centre by one eccentric; and the lead is taken from the cross-head. The two first produce by a single valve with sufficient lap, a variable expansion that is regarded as satisfactory.

There is a tendency to substitute the screw for the simple reversing lever and catch-plate. A screw, one-half which is right and the other half left, is used. The right part works in a fixed nut, so that the screw advances as it turns; and the left part works in a nut to which the reversing rod is jointed, so that this nut travels twice as fast as it would if a single screw of the same pitch were used. Four turns of the screw are sufficient to reverse an ordinary engine.

For feeding, the injector is more and more superseding pumps, even independent steam pumps. Its advantages are that it works with certainty, and needs no repairs. Herr Krauss, constructor, of Munich, has reduced this instrument to extreme simplicity. The water flows in a straight line from the tank into the boiler. There is no movable cone to regulate the influx of water; nor is there any movable coned needle to regulate the admission of steam. The steam nozzle enters the water chamber, and bends into centre line at the point best for general working, and thus the whole instrument is solid; all its parts are immovable, and there cannot be derangement from wear of packing, or other delicate and costly adjuncts of the original injector. It is screwed into the fire-box behind, and the water is spread around by the flat disc check valve inside, so that it does not flow against the fire-box plate. A cock close behind the water chamber shuts off and regulates the flow of water; and a stop valve at the boiler regulates the admission of steam, and the instrument itself is almost as simple as a cock. To start it the water cock is first opened, and then the steam is admitted gradually, after which the admission of water and steam can be regulated as required by the cock and steam valve. But it will not draw up the water; the tank must be above the level of the injector, so that the water will flow in by gravitation. The usual place for the injector is under the foot-plate.

It remains to observed that the modification of Herr Krauss' permits of feeding with hot water, an advantage which the first injectors rendered impossible.*

As to the boiler, the junction of the barrel with the fire-box shell, formerly made by an angle iron ring, is now made directly, as making the surest and tightest union. For this purpose the front plate of the fire-box shell is flanged to receive the barrel. The flanges are sharply turned. To provide ample steam room, and to facilitate the cleaning of the crown sheet, the outer crown is raised 12 to 16 inches above the barrel.

The pressure is generally $8\frac{1}{2}$ atmospheres, sometimes 10 atmospheres, on the gauge. It is subjected to severe supervision, by the aid of special manometers which show exactly how high the pressure has been. The manometers are patented by Herr Sammann, an engineer of Breslatt, and manufactured by Grutzmacher & Bock, of Magdebourg.

In the construction of fireboxes only copper plates are now used. Iron fireboxes are completely abandoned, on account of numerous inconveniences they involve. These inconveniences, it was hoped, would be avoided by using cast-steel plates, which might bear the pressure better; but the trials made have given results that are but little satisfactory. The inequality in the manufacture of these plates, which are too hard and brittle or too soft, is, without doubt, the cause of this failure. But notwithstanding the ill success, several German and Austrian companies, for the sake of diminishing the weight of their engines, persist in using cast-steel plates for the construction of boilers.

The iron boilers are made of plates .45 minimum and .62 inch maximum thickness; while the thickness of the cast-steel plates varies from .32 to .4 inch. For pressures above $8\frac{1}{2}$ atmospheres the lengthwise joints are double riveted.

The staying of the firebox, especially the crown of it, merits the greatest attention. Besides the ordinary stays of the crown, there are 4 rods which link together the front and back plates, and 8 long rods from the back plate to the smoke-box plate. This mode of staying has always given perfect security, and never needed repairing.

The use of hollow stays for the sides of the firebox has given excellent results, and is becoming general. The perforation is an easy and sure means to detect the rupture of stays, and generally gives warning of decay before it results in rupture. To provide for cases of rupture, it is necessary to stop the holes at the inner ends, so that steam or water may not enter the firebox, and extinguish or slacken the fire.

In putting into practice this idea of perforating the stays, some difficulties were met, consisting chiefly in the drilling of very small holes, .12 to .2 inches diameter, and the whole length of the stays: but an entirely satisfactory solution was found in a machine which drilled from the ends to the centre, thus shortening the drills, and also shortening the time necessary for the work. The stay is held in a hollow arbor between the two drills; the arbor turning 380 times per minute, while the drills turn in the opposite direction 680 times, making a total speed of 1,060 turns per minute for the drilling. With this machine a man drills 70 to 80 stays per day. The machine consists of a lathe bed, on which the bearing of central arbor is fixed, and the two drilling arbors are made to traverse by a right-and-left screw.

Another convenient tool is used to cut off the ends of the stays after they are screwed in. It has two cutting knives or chisels, one of them fixed, the other moved up to its work by a screw. A washer is put on the end of the stay, to determine the length; the tool is then put on, and pressed up to the washer; the screw is then turned by a hand-lever, and the cutters approach each other, cutting off the waste end. One man cuts with this tool more than 3 men can cut in the old way, and there is no blow or strain to injure the work.

In the manufacture of tubes iron is

* Mr. James Millholland, 8 years ago, patented a modification of the injector even simpler than this. It had no break or opening between the water jet and the throat, so that there could be no overflow when too much water or too little steam was admitted. An overflow cock between the throat and the check-valve was provided to start with.

now much used. These tubes have thus far given good results. Their outside diameter is from 1.28 to 2.08 inches. The joints at the tube plates require always great care. Several trials of cast-steel tubes have given equally good results, and they allow a reduced thickness.

The wheels are generally of wrought-iron, in one piece, with the boss and counterweight. The tires are of cast-steel. Notwithstanding several cases of rupture during the extreme colds of winter, the results of cast-steel tires, in durability and economy, leave little to be desired. The use of steel less hard and brittle, in cold climates, will certainly prevent ruptures.

The forges of Borsig, at Berlin, have acquired a high reputation in Germany for the manufacture of wrought-iron wheels. And so with the steel tires from the Works of Krupp, at Essen, which have furnished enormous quantities for all parts of the world.

Disc wheels with circular corrugations are frequently used on tenders. They are of cast-steel, in one piece, tire included. They have certain advantages as compared with other wheels. They are made by the Company of Mines and Steels of Bochum in Westphalia.

It is necessary to observe that these wheels, like those with steel tires, have inconveniences as well as advantages. It is necessary to true the tires or rims that have lost their shape. To do this, instead of turning them, the Cologne and Minden Railway Company use grindstones. The wheels are put in a lathe, and made to turn slowly, about once per minute, while a grindstone turns against the rim about 500 to 800 times per minute, according to its diameter: 500 turns for a diameter of 25 to 30 inches. The stones are coarse-grained, about 4 inches thick. They work best dry; but when used dry, it is necessary, for the health of the men, to use a fan to blow away the dust.

The axles of the German engines are all of cast steel; so are the connecting-rods, and generally the coupling-rods, and also the other chief parts, as the engines of Borsig have shown us. Steel allows great reduction of dimensions, and the attainment of extreme lightness—an essential condition, especially for high-speed passenger engines.

The pistons are of wrought-iron, forged on the Swedish system, often in one piece with the piston-rod. Two packing rings are used, sometimes of cast-iron, sometimes bronze. A counter piston-rod (contre-tige) is frequently used. These counter-rods are sometimes of cast-steel, and forged solid with the piston.

The speed of pistons varies between 6.4 and 8.8 inches per second. Though this speed is far from the maximum, it is rarely exceeded up to this time.

The question of the lubrication of valves, also of pistons, has much occupied engineers; and has been practically solved by the system of Kesler. This system, which works automatically, and very regularly, is applicable to many uses, and appears to save a third of the oil, while it insures abundant lubrication.

The diameter of steam cylinders is from 13 to 20 inches. The length of stroke is from 20 to 25 inches, and rarely attains to 28 inches. On these dimensions, that is, on the volume of steam used in a given time, depends the force of the engine. Very intimately connected with the cylinders, relatively to the work to be done, or that which comes to the same thing, the quantity of steam to be used, is the heating surface which produces the steam. The surface is made as large as possible, and varies between 914 and 1,882 square feet of which $\frac{1}{10}$ to $\frac{1}{18}$ is fire box surface.

The grate surface, generally arranged for common coal, is equal to from $\frac{1}{65}$ to $\frac{1}{90}$ of the heating surface. For wood the grate surface is still larger.

Among the numerous inventions to burn smoke, that of Tembrink-Bonnet has had many applications; and has given good results, especially when the feed-water has been good. Thierry's system has equally been applied. But no decision has been made, relative to the general application of these systems.

A good disposition of the chimney, relative to the draft, to stimulate the generation of steam as much as possible, is very important. To this effect the system of Prussman, composed of two truncated cones united at their small ends, is frequently applied. This seems much like the blast pipes in many English engines.

As to the weight on driving wheels, it

is admitted generally, for rails 5.2 inches high by 2.4 breadth of head, that 13 tons (13,000 kilog.) should be the maximum weight for axle; consequently the number of coupled wheels, whether 4, 6, or 8, to utilize the weight for adhesion, constitute the foundation of the power of the engine; that is, they determine the loads that can be drawn up the grades that have to be surmounted.

To couple more than 3 axles, or 6 wheels, does not appear very practical, on account of the too many joints between them, giving rise to complicated construction, and the liability to rapid wear on short curves.

Some constructors have renewed the attempt to utilize the total weight of locomotives for adhesion; and with this view they have constructed engines with only two axles. In this plan there are great difficulties to be overcome, which will ever remain a serious obstacle, above all to freight engines, in which it is required to obtain a maximum of weight for adhesion.

Tank engines do not appear to be economical, except for short lines, or for switching. The diminution of weight as the water and fuel are consumed renders them extremely defective for long lines.

A system of construction of locomotives very frequently followed of late years, deserves to be mentioned here. We speak of the system of Hall, which is distinguished by putting the frame plates outside the wheels, instead of inside, as in usual practice. This disposition gives room for a wider firebox, and allows the boiler to hang lower, and to rest on a wider spring base than usual; the two last are important advantages, since they insure a steadier movement by avoiding lurches.

Among the objections to this system, it is urged that the diameter of the axles must be augmented, and that the overhanging ends have considerable weight, and that the axle-boxes are heavier, and that, as these parts act directly on the rails, without the intervention of springs, this increase of weight is the more injurious. Also the outside cranks, whose hubs, lessened in diameter, extend inward and serve as journals, offer difficulties; and, altogether, there is little confidence in the surety and solidity of the construction. But these inconveniences do not appear well founded beyond a certain point.

As to the outside crank, the Universal Exhibition showed some modifications of it, by the Meyers, engineers of Mulhouse, which offer the best solution of this inconvenience, objected to in Hall's Meyer forges the outside crank solid on the axle, and makes the eye of the wheel so large that the crank can be put through it.

The widths in these engines are as follows for German railways: For 6-coupled freight engines, between the centres of wheels or rails, 60 inches, between the frame-plates or springs, centres, 71.68 inches; between cylinder centres, 93.28 inches. For passenger engines with independent wheels, between wheels and frames the same as above; between cylinder centres 86.88 inches.

Several other systems to ascend steep grades have been tried. We observe among them a disposition having some analogy to the chain warping on the Seine. It consists in laying between the rails, for the whole length of the incline, a strong plaited rope, which winds around the driving axle, (a separate axle specially for the rope?) in the same way as in the warpers. The rope in unwinding resumes its place between the rails, and may serve for several trains at a time.

A more advantageous arrangement, though very complicated, to increase the adhesion, is that after Fell's system which is in practice on Mount Cenis. In this system a third rail, raised higher than the two others, is placed between them, and four horizontal driving wheels, two on each side, are strongly pressed against the middle rail by spiral springs.

The engines with 8 and 10 coupled wheels, with the front group movable sidewise, of the system of Ergerth, Fink, and Hall, constitute also a powerful means often employed to ascend very steep inclines.

From what has preceded, it results that the good arrangement of a locomotive having sufficient boiler, and cylinders and wheels well proportioned, must be judged by the relation existing between the total weight and the weight utilized for adhesion. This condition is essential for freight engines that draw heavy trains, in which all weight not utilized for adhesion is dead weight to be carried or drawn.

The following table gives the principal dimensions of the weight of German locomotives, which by their good results merit a report here :

	6-coupled.	4-coupled, One Axle in Front.	Mixed, 4-coupled, One Axle Behind.	One Pair Drivers.
Diameter of cylinder...	17.8 in.	16.2 in.	16.2 in.	15.68 in.
Length of stroke.......	25.12 in.	25.12 in.	23 in.	20.92 in.
Pressure..............	8½ at.	8½ at.	8½ at.	8½ at.
Heating surface........	1268.5 ft.	942.75 ft.	847.1 ft.	953.5 ft.
Diameter of wheels.....	50 in.	56.4 in.	73.2 in.	80.16 in.
Speed, miles per hour..	14	18.6	27 to 37	47 to 56
Weight on drivers	37½ tons.	24.4 tons.	18.5 tons.	13 tons.
Total weight.....	37½ tons.	31.2 tons.	29.5 tons.	29.5 tons.

The 6-coupled engine can draw on a level 1,100 tons at 14 miles per hour. It has axles and tires of cast-steel; wheels, rods, and tubes of wrought-iron; firebox of copper; and costs about 69,000 francs. The 4-coupled, with leading wheels independent, can draw 650 tons at 18.6 miles per hour on a level. The axles and tires, etc., are like the one above, and it costs 63,500 francs. The mixed 4-coupled, with trailing wheels independent, can draw 350 tons on a level at 27 miles an hour. Parts of the same material as the foregoing, except the coupling-rods, which are made of cast-steel, on account of their great length. The engine with a single pair of drivers, can draw 150 tons at 47 miles an hour. Axles, tires, and rods of cast-steel: cost 62,000 francs.

GENERAL McCLELLAN is to complete the Stevens Battery for the State of New Jersey, as provided for in the will of the late Edwin A. Stevens.

PUDDLING MACHINES—RESULTS.—Up to the present time, as we are informed by Mr. Menelaus in papers read before the Society of Mechanical Engineers, the results of mechanical puddling are unsatisfactory, inasmuch as the iron produced has been cold-short, and unfit for use. This failure is attributed by Mr. Menelaus to the breaking up of the lining of the furnace. The suggestion was made that the uniform quality of the iron produced with differing linings pointed to some other cause; but, as far as we know, no suggestion was made as to the direction in which to seek the cause of failure.

The one chief feature in successful puddling on the present plan consists in protecting the molten iron from the direct action of the flame by a supernatant mass of molten scoria, whereas in the revolving puddling furnace the iron would appear to be lifted from beneath the scoria into immediate contact with the flame. It would be reasonable, therefore, to expect an appearance and quality similar to what is known as burnt iron.—*The Engineer.*

MAGNESIA CRUCIBLES.—The great and constantly increasing cost of crucibles, is the greatest obstacle in the way of the crucible steel manufacture in this country. A patent has been taken out in France for making crucibles to melt platinum, iron, or steel, from magnesia. The description given is not very clear; but we believe they are moulded by pressure, and are then exposed to the heat of an oxy-hydrogen flame, by which they are brought to a semi-pasty condition, and the magnesia acquires its greatest density, cohesion, and hardness. Such crucibles are said not to be affected by sudden alterations of temperature.

UNEMPLOYED MOTIVE POWER.—The "American Artisan" calls the attention of inventors to the great powers that are, so to speak, going to waste—among them wind and tide. The want is, efficient mechanical appliances—the power is almost infinite. Captain Ericsson, has attempted the utilization of what would seem to be a more impracticable motor still—the direct heat of the sun, but with great promise of success.

BUILDING AND FACING WITH CONCRETE.

Translated from La Houille for the London Colliery Guardian.

The walling of the sides of shafts in places where the rocks are not sufficiently solid, or possessed of sufficient resisting power, is commonly composed of either stone or brick. During recent years various parties have begun to make use of conglomerate concrete, a purely artificial material, for building, which is simple as regards the process of preparation, and easy to be used, while at the same time presenting a great resistance and perfect impermeability, which latter quality renders it extremely valuable for works that are in contact with water. Amongst the structures raised of late years presenting a certain amount of importance, and in which the conglomerate concrete has been employed, we may specify many buildings at St. Denis, the drains of the new Opera House, the Church of Vesinet, the vaults of the subterranean galleries of the Exhibition, the breast wall of the Avenue l'Emperor, from Pompe to the lamp beyond the Military Bakehouse. At the present moment they are constructing with this concrete, to the height of above 15 metres, the sloping boundary wall of the ancient cemetery of Passy. The concrete used is a cement rather than concrete proper. It is composed by the very intimate mixture of the following elements in determined proportions, thus :

Large sand, very pure	4 parts.
Lime	1 "
Portland cement..........	$\frac{1}{2}$ "

Water $\frac{1}{10}$ of the total weight of the mixture.

Instead of making with the sand and lime a mortar in liquid batter, the preparer must reduce as far as possible the quantity of water, and subject the mixture to an energetic and prolonged course of trituration. By this trituration, notwithstanding the great reduction of the water, there is at length obtained a dusty paste, which, after a continued process of pounding, is brought into the state of very stiff plastic paste. This is poured out into a movable mould in successive and very thin layers, and subjected to very serious pugging. This pugging effects such an agglomeration that there enters into each cubic metre of masonry from 14 to 15 hectolitres of the mixture, while the mass itself acquires a considerable rapidity and intensity of hold ; so much so that some few days or even hours suffice to give it the consistency of stone. Now, as the work done one day becomes perfectly consolidated with that of the day before, it follows that the mass of masonry may be indefinitely extended, so as to form one actual block of stone which offers a perfect resistance to frost and heat. This concrete thus forms a veritable stone paste, to which, by means of moulds, all sorts of forms may be given, and which will not present any joint, but possesses throughout a solidity not otherwise attainable. In order that the conglomerate concrete may present all the required conditions of resistance and of serviceable usage, it is necessary that the preparation should be well made. It consists of the following process : 1st. The greatest part of the water contained in the common mortars as concrete must be got rid of. 2d. The substance must be homogeneously and intimately mixed, notwithstanding the elimination of the water, by being subjected to a trituration energetic, prolonged, and operating with compression. 3d. From this trituration there must result successively a condition of hard plasticity, a pasty powder, and then a dusty paste. 4th. Agglomeration is next to be produced by the action of a hard and heavy body operating on thin successive layers poured out in proportion into a mould. By fixing movable moulds on the actual masonry, which it is required to raise to a further elevation, we may indefinitely augment its mass, and obtain, so to speak, stone without limit which advantageously takes the place of hewn stone and brick. The concrete, set under favorable conditions, offers a great resistance to picking or wearing of any kind, and its resistance to crushing reaches to from 400 to 500 kilog. per cubic metre. With regard to its producing or net cost price, it will vary in different localities, and will mainly depend on the rate of wages for manual labor. We are persuaded that this concrete can be advantageously employed in mines, its imperviousness to water and its power of resistance suiting it even for bottoming in crossing watery strata. Shafts walled with concrete would resist better and for a longer time than those faced with stone or even brick, by reason of the intimate union of its constituent elements and of their adherence to the bare surfaces which require to be faced. The facing of galleries, the fixing of conduits for water and for air, may also be done in concrete, and any movements in the earth will only produce therein fissures that may be easily repaired and filled up again with the same concrete, which will at once become incorporated with the old mass. The facing of shafts especially may be effected with great facility and great regularity. It would suffice, in fact, to suspend from a certain special rope, well fixed over the middle of the shaft, a box with very smooth exterior sides, of the diameter to be given to the shaft requiring to be faced, and behind this they could pug the concrete. As soon as a certain elevation had been attained, they could raise the box, pug anew, and so continue until they had reached the summit of the structure.

THE LOCOMOTIVE BUILDERS MEETING, recently held in New York, will, it is hoped, lead to better results than the meeting of 1856. If the builders had carried out the ideas of price and pay they all agreed to in '56, they would not have met with the general disaster that befell them in the autumn of '57. It is for the interest of railway companies and the public that locomotive builders should have no excuse for turning out inferior work. The American builders have done vastly more than the railway managers, to reduce the working expenses of engines. They deserve a reward for so greatly improving the American Locomotive, and they should have an inducement to perfect it. But they must build cheap and old-fashioned machinery, if railway managers will pay for nothing better.

STEEL-COVERED AXLES.—It is proposed to heat old axles red hot and to cast steel rings upon their journals or upon the whole axle. The steel is expected to unite firmly with the iron, and to be sound enough to finish well. This result can perhaps be realized after some expensive experimenting. Steel rail ends have been successfully cast into the centre of steel ingots, at the Pennsylvania Steel Works.

RAILWAY ACCOMMODATIONS.

This branch of civilization, says the "New York Times," is advancing perhaps more slowly than railway safety. But it does advance. Smoother permanent way, high and ventilated car roofs, the equalization of load on spread and elastic trucks, better ballasting and less dust, sleeping cars in many of which one can sleep when sufficiently fatigued, compartment cars well upholstered, better motive power, and hence closer connections, and some improvements in ticketing and checking, are the actual and comfortable facts of to-day, instead of the almost chimerical dreams they were a decade ago.

But let no railway manager suppose that he has earned immunity for another decade. Great improvements are still to be made in railway accommodations. Ventilators, for instance, are all very well, but ignorant and careless brakemen opening or closing them without reference to temperature or wind, in many cases convert them into a nuisance. Nor should officious or selfish passengers be allowed to regulate these matters. Here a brawny lumberman throws open every sash and panel on the windward, to the peril of invalids and children. There a hypochondriac seals up every aperture, to the peril of the general health and temper. There should be in every train, for invalids, infants, and old women of both sexes, who have no lungs, a compartment, ventilated as far as compatible with the exclusion of that arch-destroyer—Draft. And there should be an officer charged with the ventilation of the train—an officer who can distinguish between atmospheres of carbonic acid and air, and who can appreciate a calorific change when he enters from the out-door temperature of 40 to the internal heat of 100. And the ventilation should be under his exclusive control. The brakemen who periodically rush through a train, shutting every aperture that was open and opening those that were shut, are wonderfully innocent of all thermal and atmospheric distinctions.

But the grand discomfort, as well as the awful peril of our railway appointments, is warming the cars by stoves. If the recollection of freezing feet and aching head all the long winter evening by the railway fireside, does not throw the reader into a cold sweat, the remembrance of Angola will. There is, perhaps, no developed plan that will keep the temperature of a packed car, with constantly opening doors, as regular and pure as that of a Fifth-avenue drawing room—never below 65° or over 70°. The genius of invention may be equal to the task, but we consider the conditions absurd. When travellers are used to it they will vastly prefer the natural temperature of the outer air, modified by shade and draft in summer, and by a little artificial heat in winter; they will prefer to adapt their clothing to such an atmosphere, *provided always the feet be kept warm*, rather than risk the foulness and local heats of an attempted drawing-room temperature. We find a positive enjoyment in breathing the crisp air of an October morning, when we bundle up our persons to resist it; but the same temperature in a railway car would set the women distracted.

Another error lies in the provision of unsuitable means of warming. The American stove heats the head, while the feet remain in a cold stratum constantly re-enforced from opening doors. The use of *tanks of hot water* under the feet, preserves the temperature of every part that cannot be adequately clothed, and mollifies the general atmosphere without poisoning it. Any feasible distribution of heated air, cannot prevent the universal misery of cold feet. The present system of running to the stove to toast them, and back again to escape the headache, is better than any system of moderate heating by stoves. The calorific contrivance, whatever it may be, must lie *under the feet*. And hot-water tanks, changed at water stations, would probably, in effectiveness, certainty of operation, cost, and expedition, excel all other heaters. Water is admirably adapted for this purpose. It has the greatest capacity of any substance for holding heat, and its fluidity renders it the easiest of all substances to handle. By means of little doors in the sides of the car, between the seats, a couple of porters could change the tanks every 30 to 50 miles, as the weather might require. In case of collision, the wrought-metal tanks would be unlikely to burst, and there would be no setting fire to the *débris*.

Baker's system of warming cars by water in pipes is already used in the best drawing room and sleeping cars, both of East and West. The heat is pleasant and temperate, and it is applied where it is wanted—at the bottom of the car—at the feet of the passengers. Of the apparatus, the "Chicago Railway Review" says: The principle is very simple—that of the circulation of hot water. From the water-enclosed furnace, placed at one end or suspended underneath the car, the hot water—charged with 33 per cent. of salt, to at once prevent freezing and increase its capacity for retaining heat—flows out through the pipes distributed along the floor of the car, returning automatically to the furnace as it becomes cool. The apparatus would be little liable to accident from fire in any case; and, to make assurance doubly sure, the water surrounds the fire, so that in case of accident, it would put it out. The economy of fuel (three-fourths) and labor is extraordinary—the furnace being filled, for instance, at Chicago, locked up, and requiring no further attention till Buffalo is reached. In another important respect, the economy is notable, as compared with the stove-heated car. Instead of two stoves, one furnace is used. As this (placed in one corner) gives out no heat directly, there is a practical saving of 6 seats in each car—a common stove not only occupying the place of a single seat, but rendering the two adjoining seats uncomfortable.

A new method of heating cars, tried on the Connecticut River Railroad, is thus described:

A bonnet is placed on the top of the car at each end, to catch the wind while the car is in motion; the air rushes down a pipe into a water box, where it is thoroughly washed, and thence into a hot air-chamber surrounding a stove, whence it is forced in a pure state into pipes that run near th efloor, the whole length of the car, on each side and under the seats. At proper intervals these pipes are perforated with small holes, through which the heated air escapes. The warmth is distributed equally throughout the entire length of the car, and coming low down towards the floor will enable passengers to always keep their feet comfortably warm.

Another much needed railway accommodation would be the timely indication of stations. On many roads stations are not habitually called out by the brakemen; on most roads they are indistinctly called; on all roads they are not called till the train stops, thus giving too little time for ladies and children to prepare to alight. And as the attendants on American trains are few, and very busy at stations, passengers must, in the majority of cases, know the station, or take pains to get out and ask, or be carried on. A revolving sign at each end of the car, legible to all, and to be set by the brakeman just before stopping at stations, would be simple and effective. Such an apparatus has been introduced on the Ogdensburg and Lake Champlain Railway. It consists externally of a box surmounted by a bell, and having a glass plate in front, under which the name of a station appears in letters of about 3 inches in length. When the train arrives at the station named on the indicator, the bell on the top of the box rings, and presently the name of the next station on the line appears under the glass plate.

Speaking of attendance, the following railway order is commended to railway managers without many exceptions. It is posted in the station houses on the Rutland Railroad, in Vermont:

"Baggage men at the depots, and men on the trains—freight as well as passenger—are expected, and are employed by this Company, not only to do their work well, but pleasantly—to give every facility to travellers, by information and by acts. Any departure from civility of conduct, and that courtesy due the patrons of the road, will render them unfit for its service, and they will be dismissed accordingly. Travellers may be unreasonable, but this will be considered no excuse for any employé to be so in return."

It is hardly necessary to add, that the Railway Dinners and Lunches of America, as well as of England, may be improved.

The "New York World" says that Mr. Charles Dickens has again set on foot in England a much-needed reform. "Mugby Junction" has done more for the railroad commissariat than all the sanitary regulations, newspaper agitation, and individual growling put together. John Bull, stung in his stomach by satire, has set to work in good earnest to reform the refreshment saloons on the great railway lines, and it now seems likely that the very simple and excellent plan of supplying "locomotive luncheons" at one station, neatly and compactly arranged in baskets, which are left at the next station, is to become general. But it is in America, above all other places, that an economical and expeditious system of victualling passengers, should be devised, for here the routes are longest and the stations isolated.

IMPROVED TURBINE.—Mr. Paul R. Hodge, of London, has designed an arrangement for counterbalancing the pressure of the water on the wheel, also the weight of the shaft, etc., also for regulating the velocity of the wheel by the governor by the assistance of a working column, instead of blocking off the water from the guide curves or delivery buckets. These, and his improved method of obtaining the guide and delivery curves, are illustrated in "Engineering" of October 30 last.

There are two *improved Fourneyron wheels* on one shaft, one working above the casing and the other below; inside the casing there are the two sets of guide curves answering to each wheel. The pressure of water due to the head or column is counterbalanced by the introduction of the second wheel above, thereby effectually taking the pressure off the step of the shaft.

The manner of regulating the wheel by the governor is as follows: The governor operates on a vertical rod, to which is attached the balanced sluice or puppet valves for the regulating of the quantity of water in its passage from the reservoir to the working column at some distance above the wheel, so that if, when the wheel is working at its maximum of effect, a certain portion of the load is suddenly thrown off, then the sluice valves close and the working column is reduced to an extent corresponding to the reduction of the load on the machine. When an increased load is again thrown on, the governor reopens the valves and admits water corresponding to the increased load. By this arrangement the objectionable methods of blocking off the water from the wheel, either by the guide curves or delivery buckets, is done away with, it being a well-ascertained fact, that, when 10 per cent. of water is stopped off by the latter method, there is a loss of at least 30 per cent. of effect.

IRON AND STEEL INSTITUTE.

The ironmasters and steel manufacturers of Great Britain have resolved upon forming an "Iron and Steel Institute," for the discussion of questions of practical and scientific interest. The general principles of the proposed Institute will be similar to those adopted by the Civil and Mechanical Engineers, and other kindred societies, all questions bearing on trade regulations and wages being rigidly excluded.

From the number and position of the gentlemen who have taken an interest in the project, no doubt need now be entertained, says the "Mining Journal," of its being carried to a successful issue. Each of the ironmaking districts is well represented, as will be seen from the subjoined list of appointments to the provisional committee which have been made :

North of England.—Messrs. Edward Williams, Isaac Lowthian Bell, David Dale, James Morrison, B. Samuelson, M. P., W. R. Innes Hopkins, Charles Bagnall, M. P., John Jones.

West Coast.—Messrs. Joseph T. Smith, W. Fletcher, John Lancaster, J. Paterson, James Smith.

South Staffordshire.—Messrs. G. J. Barker, Walter Williams, William Matthews, John Hartley, William M. Sparrow, Frederick Smith, Saunders, Sampson Lloyd.

North Staffordshire.—Messrs. W. S. Roden, Robert Heath, J. Udall, J. Ramsbottom.

South Wales and Monmouth.—Messrs. W. Menelaus, A. Brogden, R. Fothergill, Budd, Abraham Darby, Struve.

Shropshire.—Mr. Thomas Horton.

Sheffield (Steel).—Messrs. Henry Bessemer, Edward Vickers, George Wilson, Mark Firth.

West Riding.—Messrs. F. Kitson, Jefferies, John Butler.

Derbyshire.—Messrs. J. G. N. Alleyne, William Fowler.

Scotland.—Messrs. Walter Neilson, Whitelaw, R. Cassels, Robert Hannay, Neil Robson.

It is gratifying to find that there appears to be every disposition on the part of the provisional committee to make the institution that which it professes to be —a national association; and with this view it has been decided that the makers of iron and steel in the several districts shall be asked to become members, and that the headquarters of the proposed institute shall be London, periodical meetings being held in the various ironmaking districts. By this means will be removed all cause for little jealousies which might arise from a particular producing district possessing the advantages of being the seat of the society's headquarters. Such associations as the Iron and Steel Institute are well calculated to promote the material progress of the branch of industry with which they may be connected, and it is to be hoped no time will be lost in bringing the project into working order.

THE CHENOT STEEL PROCESS.

Removing and treating the pure iron from a blast furnace before it becomes carburized, has been the subject of some experiments, many schemes, and great expectations. The scheme of M. Chenot is well described by M. Laudrin in his treatise on steel, but its practical and commercial prospects are not hopeful.

In the ordinary blast furnace where pig iron is produced, there are two distinct operations at two different heights of the stack. The iron ore, which is a compound of iron, oxygen, and earthy matter, is reduced in the upper parts of the furnace after somewhat complex reactions. At a certain height the ore comes in contact with carbonic oxide, which unites with its oxygen, and escapes at the mouth as carbonic acid. The earths which accompany it become separated, and fall to the lower part of the furnace, where they are transformed into slags or cinders. The iron is reduced, and remains pure. The height where these reactions occur is termed the zone of reduction; the heat is intense. At this point let us see what happens. The carbonic acid escapes at the top of the furnace, the iron and slag remain, and, on account of their specific gravity, fall to the lower part of the furnace, where the temperature is greater, and there undergo new reactions. Every one at this stage of the operation will think it would be more advantageous to extract the perfectly pure iron instead of allowing it to fall among the incandescent coals, where it is transformed into carbide or pig iron. Such was the idea of

M. Adrien Chenot, who thought of stopping the operation just when the ore had been converted into pure iron. An intense heat reigns in the greater part of the furnace 16 feet above the zone of reduction, and 33 feet underneath. Why should such a heat be kept 10 metres under the point where the pure iron is obtained? We readily understand that, when pig iron is wanted, such a heat is maintained underneath in order that the iron shall be converted into pig metal in a carburizing atmosphere. But, when ductile iron is wanted, we think it is useless and costly to keep up the combustion of the fuel when the product sought for is already obtained. Following these principles, M. Chenot, instead of heating the furnace underneath the boshes, that is, the lower part, has directed the highest temperature to be applied at the zone of reduction. The combustion ends there. The pure iron thus produced descends gradually into cold boshes, where it cannot undergo any new reaction, and where it is found in spongy masses mixed with the earths. The only operation which remains is the separation of the iron from the earths. This is effected by powerful magnets, which, being presented to the cold and pulverized residue, separate the iron in a state of perfect purity. This powder of pure iron being submitted afterwards to an enormous pressure which reaches above 700 atmospheres, has its atoms so strongly united that it acquires the density of iron itself, and may be drawn into bars, and undergo all the operations of a forge.

The compressed sponge is used by M. Chenot for cementing iron, and conversion into steel. It has been found by experiment to absorb its own volume of liquid; therefore it is sufficient to dip it into an oleaginous liquid, as coal tar, in order to produce a true carbide, not by combination, but by mixture. The metallic mass thus impregnated is put into pots and cast in the usual way.

EFFECT ON CLIMATE AND LAND, OF OPENING THE SUEZ CANAL.—In his address before the British Association, Mr. Bidder called upon it to get information as to the effect of filling a lake (now dry) of 150 square miles extent, and thus adding 2,500 cubic feet per minute to the evaporation, equal to a rainfall of 365 inches per annum.

RAILWAY BRAKES.

No sooner was the problem of setting trains in motion by steam satisfactorily solved, than a more difficult one, that of arresting their motion, arose in its place. It is not too much to assert that, in spite of the innumerable patents taken out, inventions experimented upon, and trials undergone, the question of obtaining a perfectly satisfactory brake action is yet an undecided one. Probably, the real reason why the difficulty has not been overcome, is that too much has been sought for, and too rigorous a solution of the problem attempted. Inventors, as a rule, have striven, with inexhaustible patience and assiduity, to design a brake that will stop a train almost instantaneously, and those who have effected the change from rapid motion to a state of complete repose in the shortest time, have considered that they have approached nearest to the vanquishing of the obstacle. But in fact they were very far from attaining the desired result. The great object of a brake is not to suddenly and totally arrest the progress of the train, but to gradually reduce it to a state of rest. It is not expected to act only on rare and special emergencies, but to be of continual use during the whole journey. In a word, it is for general, and not special employment. In order to obtain a sudden arrest of motion, all the earlier, and most of the recent, descriptions of brake were made to lock the wheels immediately upon their application. Independently of the great impactive force suddenly brought into play, and the violent torsion thrown upon the axles by this arrangement, it is radically unsound in principle, and does not effect the result desired. If the skids (brake blocks) press so tightly upon the wheels as to lock them, the train is not brought to rest so soon as if they only had bite sufficient to prevent them from revolving. To determine theoretically the exact velocity at which a body will cease to roll and commence to slide, is a very nice mathematical problem, but practically the limits may be ascertained experimentally with sufficient accuracy for all working purposes. At the late Exposition, the improvements in the details of brake gear were mostly confined to effecting the instantaneous application of the skids to the wheels. These comprised the use of levers, screws, springs, balance weights, and other contrivances, including automatic and electrical agencies.—*Mechanics' Magazine.*

We think the requirements of a brake are correctly stated above, and we would call the attention of English railway managers to the American Creamer brake, which we think fulfils these requirements in a marked and useful degree, if not absolutely.

THE GAS MANUFACTURE.

Compiled from a paper by Mr. Gore before the Society of Engineers, and from the address of Mr. Barlow before the British Association of Gas Managers.

Among the varied applications of scientific discovery to the purposes of daily life during the last century, few, if any, have attained greater importance than that which relates to the manufacture and application of coal gas. Scarcely a city, town, or village, of considerable size, in this country, or on the Continent, or even in the United States of America, remains unsupplied with this almost indispensable agent, in our industrial and social existence. Its use is rapidly extending in more remote regions, for strange as it may appear, there are many peoples and communities who, though persistently resisting useful applications of practical science as dangerous innovations, are yet eager to avail themselves of the use of gas as a source of artificial light and heat. Even religious prejudices of the most obstinate character have succumbed to this desire, and we now behold the Christian Church, the Mosque of the Mahometan, the Hindoo, Buddhist, and even the Chinese Temple, each illuminated by this simple yet beautiful light.

Composition of Coal Gas.—In the absence of any other well-supported theory, it is the generally received opinion that the light afforded by this gas is due to the amount of solid carbon incandescent in the flame at the moment of combustion. The two most important gaseous compounds of hydrogen and carbon, are marsh gas, or light carburetted hydrogen, and the other olefiant gas. The composition of the first is represented by the symbols $C\ H_2$, and consists by weight of 75.4 of carbon, and 24.6 of hydrogen. The composition of the second is represented by the symbols $C_2\ H_2$, and consists of 86 parts of carbon and 12 of hydrogen. The permanently gaseous constituents of all coal gas consist essentially of combinations of these two fluids or compound gases; but experiment shows that it is not a chemical union that is formed between them, but simply a mechanical mixture that takes place. Thus some coal gas of low illuminating power consists principally of marsh gas, with a very slight proportion of olefiant gas; other gas, of high illuminating power, contains an excess of olefiant gas. But the value of gas as a source of light is not due entirely to its gaseous constituents, for it almost always contains a certain quantity of vapors, more or less rich in carbon, and therefore extremely valuable as light-giving agents.

Quality of Gas.—What is technically called a poor gas coal always yields gas of the most permanent character, and is the most uniform in its amount of illuminating power, owing to the small amount of hydrocarbon vapors, and hence the small mechanical mixture. With a coal rich in the constituents of olefiant gas, the illuminating power, though actually much greater, is still liable to more variation than is the case with the poorer gas; but the greatest instability is experienced when a mixture of poor and rich coal is used. The gases generated from this mixture form but a feeble combination, the one with the other. The hydrocarbon vapors are merely held in suspension, and do not enter into union with either of the gases; the slightest obstruction, or the lowering of the temperature, soon destroys this slender connection, and the result is the loss of a very considerable portion of the illuminating elements of such gas. It is strange yet true that this last process of manufacturing by mixed material is the one very generally adopted.

Quantity *vs.* Quality.—In the earlier years of gas lighting illuminating power was not regarded of any great importance. And when opposition was raised it was almost always on the ground of price. This led to the establishment of the Great Central Company for the supply of the City of London, upon the fundamental principles of a low price and a low standard of illuminating power. To carry these proposals into practice involved some important modifications and changes in the machinery and apparatus. The principle laid down in the case of the Great Central Company has been more or less applied throughout the country, and the result has been that the constructive details of gas works have been carried out almost exclusively with a view to obtain the largest possible *quantity* of gas from the materials used for its production. Furnaces affording the greatest heat, retorts exposing the largest carbonizing surface, condensers and scrubbers making the strongest ammoniacal liquor, purifiers of large capacity and surface for the oxide system of purification, monster gas-holders, and last, though not least, street mains of the dimensions of small tunnels; these, and perhaps some other matters, are the concomitants of cheap gas, as inaugurated at the period above referred to.

Subsequent events, however, have shown that at least one of the parties to the arrangement (the gas consumers) have become dissatisfied with their bargain. The Legislature has so far interfered as to raise considerably the standard of illuminating power, and the question presents itself whether, in meeting this change, it may not be requisite to modify the present mode of constructing gas works, especially where mixed coals are used.

Retorts and Dip-pipes.—In large works, and with clay retorts, the system of through setting, with double mouth-pieces, is unquestionably the most economical, both as regards fuel and durability. But this arrangement is open to grave objections. If the retorts are used for the generation of gas of high illuminating power, the increased surface over which the gas passes after it is eliminated from the coal exposes it to the chance of decomposition, and the consequent deposition of its carbon. In through retorts this deposition is due mainly to two causes; in the first place, in charging the retort, the centre scarcely ever receives its due portion of coal, and as this part is always the hottest, it follows that the gas generated from the thinner stratum of coal is exposed to intense heat, and a portion of it is speedily decomposed. Another cause of this deposit is the want of uniformity in the pressure in the two hydraulic mains; a slight resistance in one main or the other causes the gas to take the course offering least obstruction, and as the particles of gas thus pass over a larger amount of heated surface, they are exposed to the greater risk of decomposition. Several expedients have been suggested to remedy this evil; one is to use a valve to each ascension pipe, so as to dispense with the dip-pipe when the retort is working; another is to have only one hydraulic main, placed over the centre of the ovens, and both mouth-pieces connected to it by a single dip-pipe.

Some farther modifications made in the form and arrangement of the dip-pipe tend to remove the inconvenience that arises from the necessity of having the dip-pipe sealed in the hydraulic main. An American inventor has suggested an alteration in the old form of hydraulic main by casting the dip on its side. This method of forming the dip-pipe presents some advantages in clearing out, and it avoids the inconvenience attending the collection of pitch round the mouths of the pipes. A more important arrangement of the dip-pipe, having for its object the removal of the pressure in the retorts occasioned by the seal in the hydraulic main, has been contrived by Messrs. Cockey & Sons. This arrangement is called a "telescopic" dip-pipe, that portion of it which enters the tar in the hydraulic main being made to slide up, like the tube of a telescope, as soon as the retort is charged; the action taking place by means of a lever to which a handle is attached. Before loosening the lid of the retort the telescope part of the pipe is lowered again into the tar to prevent the gas from passing back into the retort.

Machines for Drawing and Charging Retorts.—Of the mechanical appliances for the charging of retorts, by which a large system of retorts set in one oven may be charged at once, by a number of scoops operating at the same instant, Mr. Barlow says: The plan has been practically tried at the Alliance Gas Works in Dublin, and I am able to speak of it very favorably. A new retort-house has been erected, capable of carbonizing 300 tons of coal in a day, and containing 270 double retorts, or 540 mouth-pieces, the charging and discharging of which is performed by two machines, and hitherto with complete success. Best & Holden's "steam stoker," as the machine has been termed, appears to be destined to make a revolution in the retort-house arrangements of all large gas works. The patentees have contracted for the charging and discharging of the retorts at the rate of 9d. per ton, including royalty, the cost under the old system having been 1s. 7d.

The Condenser.—By the term condenser, we usually understand the apparatus acting as a means of refrigeration, but this is only true in reference to its use where the gas is of poor quality and of low specific gravity. In treating gases which are to possess high illuminating power, it is not desirable to reduce their temperature below 60 degrees. Under these circumstances, therefore, we must look upon the condenser as a seperator, and not simply as a refrigerator. The two forms of condensers most generally in use are the tubular, or series of pipes, and the annular. Whichever of these forms is adopted, a large extent of surface is indispensable, in order that the separation of the mechanical and non-chemical impurities contained in the crude gas may be gradual. The existence of naphthaline may in many cases no doubt be traced, first, to the high temperature at which the gas is generated, and again to the too sudden reduction of the temperature by rapid and excessive refrigeration. It is a strange anomaly that so much care and labor should be applied to remove so many of the light-giving constituents from the gas, and then to give back these elements by the use of costly, and in some cases dangerous appliances, in naphthalizers, carburetters, and other high-sounding and wonderful specifics.

Washing Gas.—After leaving the condenser the gas is subjected to washing, either by means of the old-fashioned wash-vessel, or the more modern "scrubber;" the object in either case being to purify the gas from any remaining particles of tar, heavy oils, and ammonia. Many very conflicting statements have been made in reference to the effect of water in removing some of the light-giving constituents from coal gas. Several chemists, who have the reputation of being oracles in these matters, have asserted that water exerts but a small influence in diminishing the illuminating power of coal gas. Some engineers, who certainly have an equal claim to consideration from their great practical experience, say, on the contrary, that water produces a very injurious effect. Mr. Gore here gives, at length, certain experiments which seem to prove the latter proposition, and says that after a series of trials, a system was adopted of allowing the water to flow through the scrubber for ten minutes, at intervals of two hours; the gas was sufficiently freed from tarry matter, and the illuminating power of 19 candles was always maintained, the average being 21 candles at the works.

Lime *vs.* Oxide of Iron.—In removing from gas the chemical impurities, lime is unquestionably the most appropriate agent, and, in all situations where it is possible to employ it, it should be used to the exclusion of all other substances. Considerations of economy, and certain sanitary regulations, have induced chemists and engineers to turn their attention to some of the metallic oxides as substances adapted for the purposes of gas purification, and now by common consent certain oxides of iron are used as a substitute for lime in most of our important gas works. The action of this material is to remove the sulphuretted hydrogen, by the union of the sulphur with the iron, forming the black sulphuret or sulphide of iron. When the material is fully saturated, it is removed from the purifier, and on exposure to the atmosphere undergoes a series of chemical changes, which result in the precipitation of the sulphur and the re-oxidation of the iron, which again becomes fitted to act as a purifying agent; in fact, the process of revivication may be carried on for months before the purifying power of the material is entirely exhausted. In constructing purifiers for the oxide of iron process, a much larger superficial area is necessary than when hydrate of lime is employed. It is very questionable, the author ventures to think, whether the practice of increasing the thickness of the layers of the oxide is in all respects good, especially when the material is partially spent.

Adulterations.—A very objectionable system is now pursued in gas manufacture of disregarding the existence of carbonic acid in gas. The reason assigned for this practice is that the quantity is so small that its interference with the illuminating power of the gas is easily compensated for by adding a little more Cannel in the process of manufacture. Another economic suggestion has been made, namely, the revivication of the oxide in the purifier itself, by allowing a portion of atmospheric air to be driven through the material along with the gas, thus causing a constant decomposition of the sulphuret as fast as it is formed; the injury resulting to the illuminating power of gas is to be remedied by that panacea for most, if not for all, of the ills attendant on gas lighting—"a little more Cannel"—but any admixture of atmospheric air should certainly be avoided, first, because it is a dishonest adulteration of the gas, and, secondly, because it is unsafe, and may lead to the most disastrous consequences.

Gas-Holders.—It must be admitted that the larger the gas-holder the cheaper its cost at per 1,000 feet of its contents; but it is a question for serious consideration whether, as a matter of safety, these enormous depositories are not open to grave objections. So long as the quantity produced in the course of manufacture was the essential object of our manipulations, the effect on the quality of gas by its storage was only of secondary importance; but if a higher standard of illuminating power is to be imposed, the advantages of these enormous gas-holders may not prove so obvious. The storing of gas (especially such as contains any considerable amount of hydrocarbon vapors) is sure to result in an appreciable diminution of its illuminating effect.

Situation of Works.—In selecting a site for works, the following are among the most essential desiderata: Sufficiency of area, a low level, a good supply of water, good drainage, and easy access. In the earlier times of gas engineering it was thought desirable that the supply should be as near as possible to the centre of the consumption, but modern practice removes our gas works to remote distances, and some enthusiastic persons have even suggested the removal of the manufactories to the centres of our coal districts. Wild as this proposal seems, it might possibly be realized, if gas and not light was the product to be supplied; but if the public demand gas light, and not light gas, then the proximity of the works to the locality of the consumption must be a vital element in the economy of gas manufacture. The longer the distance through which the gas has to travel before reaching the burner of the consumer, the greater will be the loss of illuminating power; hence it follows that a company supplying gas from works three or four miles from the district or place where the gas is to be consumed, will have to use a much larger proportion of Cannel, or other light-producing material, to produce and supply gas of equal quality with a company only a mile from its consumers. It is very questionable if the advantages said to be gained in a sanitary point of view, or the greater economy effected in the delivery of raw materials, and the distribution of residual products, as coke, tar, liquor, etc., will at all compensate for the increased outlay in mains and the attendant loss of illuminating power.

New Methods for Gas-Making.—The pressure which the Legislature has recently put on gas companies to raise the standard of illuminating power considerably above that obtainable from common coal, has compelled most of them to use a certain proportion of Cannel coal at a heavy cost and with a diminution in the value of the coke. The advance in the price of Cannel consequent on the increased consumption has stimulated inquiry to find a substitute for it, and this seems to have been accomplished by Mr. McKenzie, whose process of mixing small coal with crude shale oil has been successfully adopted on a large scale at the Alliance Gas Works in Dublin. The small coal is well mixed with the oil in the proportions varying from 10 to 30 gallons to 1 ton of coals. This is effected by means of a mixing or grinding mill. The compound material is then distilled in ordinary gas-retorts of clay or iron at a strong heat approaching a white heat. From a mixture of Llantwit small coal, costing 12s. 6d. per ton, with 5 per cent. of Broxbourne shale oil, costing £5 per ton, the produce of the distillation of one ton of the mixture was—

9,750 cubic feet of gas of 21.5 candles illuminating power.

37 bushels of good hard saleable coke.

2 bushels of breeze.

11 gallons of tar.

15 gallons of ammoniacal liquor of 5° twaddle.

The cost of this mixture, including royalty, was about 17s. per ton against 24s. for Wigan cannel, over which it has the advantage of at least 5s. per ton in the value of the coke.

Two other new sources of supply of materials for producing gas of high illuminating power have been proposed—viz., New Brunswick albertite and Trinidad bitumen. From the results of experiments on the former made by Mr. Evans, at the Horseferry Road works of Chartered Company, it appears that the yield per ton is from 9,166 to 10,200 cubic feet of gas, varying in illuminating power from 23.66 to 35.42 candles, from which quantity, however, 10 per cent. must be deducted in practical operations on a working scale, and the material is offered for sale in London at 37s. 6d. per ton. Trinidad bitumen does not present quite the same advantages. When mixed with 80 per cent. of Newcastle coal the yield per ton, according to the joint experiments of Dr. Letheby and Mr. Keats, was 10,600 cubic feet of 17.6-candle gas, and it could be sold in London at from 45s. to 50s. per ton. There is, however, the serious drawback to the use of Trinidad bitumen that it contains a large amount of sulphur and water.

The "Mechanics' Magazine," refers to a number of successful experiments in this direction, but says we are making no *practical* progress; the companies are not taking up the new process, and the public are reaping no benefits. According to Mr. H. P. Stephenson, gas engineer, a mixture of 20 per cent. of bitumen with 80 per cent. of Lord Belhaven's main coal, distilled at a red heat, produced 9,072 feet of 14-candle gas. Thus a coal which is unfit for the production of gas when carbonized alone is rendered useful. Some experiments carried out at the Woolwich Arsenal Gas Works, with mixtures of coal and bitumen, showed that a mixture of 25 parts of bitumen and 75 of coal yielded at the rate of 9,856 feet to the ton of 20-candle gas. It was estimated that the cost of such gas to the consumer, the materials being furnished respectively at 32s. and 16s. per ton, would not exceed 3s. 7d. per 1,000 feet of gas sold. A long series of trials on a manufacturing scale, made by the Gas Committee of the City Corporation of London, and conducted by Professor Frankland, Mr Hughes, C. E., and Mr. Stephenson, C. E., showed conclusively that when the raw materials were supplied at the prices we have named, 20-candle gas could be sold at a large profit at 3s. 7d. per 1,000 feet. Professor Odling has also made a series of laboratory experiments upon the use of bitumen for gas purposes, with highly favorable results. Other eminent men have also made trials which resulted most favorably. Where is the hitch? Are the gas companies enjoying too comfortable a monopoly to risk a change?

Gas as a Motive Power.—The successful application of the explosive force of gas as a motive power opens an extensive field for the demand for gas for day consumption in manufacturing towns; and it is a matter of great surprise that gas companies have not made exertions to promote the use of the gas engines. Improvements have been made on the original form of the Lenoir engines by Messrs. Kinder and Kinsey, by which its power and efficiency have been considerably increased.

LOCOMOTIVE Cotton Press.—Mr. C. G. Wilson, of London, has mounted a hydraulic cotton press upon a traction engine for service in India. The engine will be conveyed on a railway truck to the various stations on the line of railway in the cotton districts, where it will remain for sufficient time to press into bales the cotton stored there; when required, the engine will proceed by its own traction power to the depots in the great fields.

The engine can also furnish power for other presses, mounted on a carriage without steam power, and may also be employed to drive cotton gins, etc., by means of belts.

After describing the press in detail, the "Mechanics' Magazine" (October 16, 1868), says: Unpressed cotton is so liable to be destroyed by fire, that one Indian railway company alone had claims amounting to £30,000 made upon it in a single year. Compressed cotton will not burn; therefore there can be no question that Mr. Wilson has, by the invention of this press, done much not only to facilitate the transport of cotton, but to cheapen that commodity in this country.

BOAT Construction.—A recent English patent specifies boats built of staves like a cask, with a central opening cut out and surrounded by a combing.

THE NITRATE OF SODA STEEL PROCESS.

HEATON'S PROCESS AND PLANT.—BESSEMER'S APPARATUS.

The Heaton process of decarburizing cast-iron, says "The Engineer," has for some time been employed on a manufacturing scale with complete success at the Langley Mill Works, Nottingham, and is competent to make remarkably fine steel and "steel iron," from the very worst and most sulphur and phosphorus-charged "makes" of iron in Great Britain, and in a word, to make excellent marketable steel from any "make" of pig iron that may be put into the Heaton converter.

This process consists in the application to the molten crude iron, of a far more powerful and searching agent than heated air—namely, the *nascent oxygen* developed at the moment of contact between the molten cast-iron and such classes of salts, nitrates, etc., as yield oxygen under those conditions. The mere idea of decarburizing crude iron by the use of nitrates, is by no means novel. Notices will be found in many old chemical works of the reactions produced by nitre upon red-hot iron.

Nitrate of soda is the form of nitre employed by Mr. Heaton. It is not decomposed in presence of fluid cast-iron with the same intense energy that nitre is, but still would prove an agent for the burning out of the silicon, carbon, sulphur, phosphorus, etc., more or less unmanageable, were it not for the extremely simple but beautifully effective apparatus invented for its application, and which constitutes, in fact, the essence of Mr. Heaton's patents. The following is an outline of the process and its results :

Pig or other cast-iron, whatever be its quality, is melted in a common iron foundry cupola with coke fuel. The liquid iron in known mass—usually from a ton at a time to perhaps hereafter as much as five tons—is tapped out into an ordinary crane ladle, and the latter is swung round to the side of the converter. The converter consists of a tall cylinder of boiler plate, open at bottom, which is supported at a certain height above the floor beneath it. This cylinder is lined with fire-brick, and above its upper part rises a cone and a funnel of plate iron, freely open at top. To the bottom of the cylinder any number in succession of short nearly cylindrical pots lined with brick and fire-clay, and in form very like crane ladles, are adjustable by simple means. Into the bottom of one of these pots a known weight of crude nitrate of soda of commerce is put ; the surface of the gross powder is levelled and covered by a pretty thick circular plate of cast-iron, perforated with many holes, which lies by its own weight upon the top of the nitrate. One of these pots thus prepared having been adjusted to the bottom of the cylinder, the converter is now ready for use. At one side of the cylinder described, is a sort of hopper funnel, covered by a loosely hinged flap of boiler plate. This plate is raised, and the ladle full of liquid cast-iron is at once poured into the converter, and so descends right down upon the top of the cold cast-iron perforated plate. The plate does not float up nor become displaced, nor does any action become apparent for some minutes, while the plate is rapidly acquiring heat from the fluid iron above it, and the nitrate getting heated by contact with it. What follows we may describe in Professor Miller's own words, from his personal observation and report :—"In about two minutes a reaction commenced; at first a moderate quantity of brown nitrous fumes escaped ; these were followed by copious blackish, then gray, then whitish fumes, produced by the escape of steam, carrying with it, in suspension, a portion of the flux. After the lapse of five or six minutes deflagration occurred, attended with a roaring noise and a burst of a brilliant yellow flame from the top of the chimney. This lasted for about a minute and a half, and then subsided as rapidly as it commenced. When all had become tranquil the converter was detached from the chimney, and its contents were emptied upon the iron pavement of the foundry. These consisted of 'crude steel' and of slag. The 'crude steel' was in a pasty state, and the slag fluid; the cast-iron perforated plate had become melted up and incorporated with the charge of molten metal."

The first product of the Heaton process, which he denominates "crude steel," is in reality malleable iron of the very purest and finest quality. The broken up lumps of this material, direct from the converter, only require, after they have been "patted" or squeezed under the "shingling hammer" to condense their spongy texture, to be heated again in a common "balling furnace," and rolled at once into bars, or forged or rolled into any desirable form. In this state the material is very unhappily called by the inventor "steel iron." It has but little pretensions to be called so; it scarcely perceptibly hardens in water. What it really consists of is crystallo-fibrous wrought-iron, almost absolutely sulphur and phosphorus free, of great strength and toughness, and for every structural purpose equal to the renowned wrought-iron produced at Lowmoor and Bowling works. It welds perfectly; it is tough both hot and cold, neither red-short nor cold-short, and forges beautifully at both the test temperatures for iron—a low red, and a clear yellow heat.

The "steel iron" is itself of course a valuable material ready for market. From this material it is, that Mr. Heaton makes his cast-steel, that is, before it has been subjected to any rolling, while in the state merely of "crude steel," patted into cakes by the shingling hammer. These cakes are broken up, put into ordinary clay melting pots of the usual size, holding about 60 pounds each. To each 100 pounds of the material, about 2½ pounds or 3 pounds of spiegeleisen, or its equivalent of oxide of manganese and a little charcoal, are added, and the whole is fused and cast into the ordinary ingots of iron. It is now excellent cast-steel, and when the ingots have been tilted in the usual manner, cast-steel bars are produced fit for any uses to which steel is at present applied. Such is the Heaton process; its simplicity and directness need no comment to those acquainted with ordinary iron and steel making.

The following analyses of the iron treated, and the resulting products are from Dr. Miller's official report:

	Cupola. Pig (4).	Crude. Steel (7).	Bar. Steel (8).
Carbon	2·830	1·800	0·993
Silicon, with a little titanium	2·950	0·266	0·149
Sulphur	0·113	0·018	traces.
Phosphorus	1·455	0·298	0·292
Arsenic	0·041	0·039	0·024
Manganese	0·318	0·090	0·088
Calcium	——	0·319	0·310
Sodium	——	0·144	traces.
Iron (by difference)	92·293	97·026	98·144
	100·000	100·000	100·000

The report also says: The chemical principle appears to be good, and the mode of attaining the result is both simple and rapid. The nitric acid of the nitrate in this operation imparts oxygen to the impurities always present in cast-iron, converting them into compounds which combine with the sodium, and these are removed with the sodium in the slag. This action of the sodium is one of the peculiar features of Heaton's process, and gives it an advantage over the oxidizing methods in common use.

Upon the appearance of the foregoing in "The Engineer," the London professional papers contained many comments by editors and correspondents, the gist of which are as follows. "The Engineer" says: Mr. Bessemer, in one of his patents, long ago claimed the use of any solid substance capable of evolving oxygen for the conversion of iron into steel; and if such a claim could be maintained, as we presume it might be, the nitrate process would be no more than a modification of Mr. Bessemer's better known system of compressed air jets. But if it be proved to have the distinctive power of removing phosphorus, it takes a still higher rank.

Professor Miller states that pig iron, containing 1.455 per cent. of phosphorus, loses all but 0.298, or say $\frac{3}{10}$ths per cent. in the nitrate converter. Yet of the 2.83 per cent. of carbon in the same pig iron, but 1.03 per cent. was removed, and 1.8 per cent. remained, and there remained also 0.266 per cent. of silicon, besides small quantities of sulphur, arsenic, calcium, sodium, etc.; so that the pure iron remaining was but 97.026 per cent., whereas in good steel it should be nearly, or quite, 99½. Every competent metallurgist will at once percieve that this so-called "crude steel" is very crude indeed—that it is, in fact, only comparable to half puddled iron, long before it has come to nature; and any one who has paid the least attention to the chemical composition of steel must be aware that samples containing 1.8 per cent. of carbon are wholly unfitted for any purpose to which steel is applicable.

Mr. Robert Mushet says: The Bessemer process converts melted cast-iron at once into steel, keeping that steel liquid until it is poured into ingot moulds forming ingots fit for drawing or rolling out into bars of cast-steel. The Heaton process takes melted cast-iron and treats it with nitrate of soda in a converter, and the result of this treatment is to deprive the cast-iron of much of its carbon, in consequence of which, as there is not, as in the Bessemer converter, any means of increasing the temperature, the iron assumes a pasty condition, and is emptied out on the floor in place of into ingot moulds. Scarcely so direct this as the Bessemer process. But now comes the cream of the joke. The pasty stuff turned out on the floor is, as Mr. Heaton properly terms it, "crude steel." (Mr. Mushet then goes on to show that it is very crude, as above explained—too much carbon and phosphorus.) Some of this pasty matter, which had been "patted" or squeezed into cakes, I found could not be forged at any temperature, far less would it weld; and when melted in crucibles, it proved considerably inferior to ordinary Bessemer scrap steel, for the manufacture of cast-steel. Dr. Miller also states that the maximum amount of slag from the converter did not exceed 23 per cent. of the weight of the metal charged. Where did it come from, if even 20 per cent.?

Mr. Mushet concludes: No one has ever doubted that nitrate of soda will eliminate, more or less, sulphur and phosphorus from cast iron, but as it does not generate a lasting and progressively increasing temperature, thereby rendering the purified metal fluid so that it can be cast into ingots, it follows that the Heaton process can never compete with the Bessemer process.

Mr. Ferd. Kohn says: The conclusions arrived at by Professor Miller are not in accordance with the theory originated, I believe, by Dr. Percy, and now adopted by the majority of metallurgists, viz., that the presence of alkaline or other basic matter during the process of decarburization has very little effect or influence upon the removal of phosphorus in the shape of phosphoric acid, but that the phosphorus is separated from the iron as phosphide of iron. This phosphide of iron is liquid at a temperature at which the malleable iron solidifies, and can therefore be mechanically separated from the iron by hammering or squeezing. Mr. Kohn then proceeds to show that Professor Miller has only accounted for 8 out of the 15 pounds of phosphorus that disappeared from the iron in the operation described. The 8 pounds were found in the slag. The remainder must have been squeezed out by the subsequent hammering and rolling, just as it would be in the treatment of puddle balls.

Another correspondent of "Engineering" says, that as some 3½ cwt. of nitrate of soda, at £10 per ton, are required for a ton of crude "coke" produced, he does not see the advantage in buying pig iron, say 30s. cheaper than Bessemer pigs, and then spending 38s. worth of nitrates for bringing out a material which is certainly not as pure as hematite pigs after all, and which you must scrape together from the floor of your forge in order to get it into anything like a workable state by a second process.

In a paper read by Mr. John Gjers before the Cleveland Institution of Engineers in April last, it is stated that several patents existed before either Mr. Heaton's or Mr. Hargreave's time, for the use of oxidizing salts, amongst which nitrates are named; and in the patent granted to Knowles, dated July 10, 1857, No. 1,921, nitrate of soda is specially claimed for refining iron, by pouring melted pig iron upon the salt in a ladle. This patent, as well as other patents for the use of nitrates, and almost every other oxidizing salt, applied both in separate vessels and in the puddling furnace, are now expired, and consequently public property. This paper also states, that as a result of analyses, this metal comes very far short of what was pretended, as nearly the whole of the phosphorus, the greater part of the carbon, and a considerable quantity of silicon is left in the metal, and very little in the slag, and that it is in every respect considerably inferior even to common refined plate.

An apparatus has recently been patented by Mr. Henry Bessemer for following out his early propositions of decarburizing iron by the use of substances capable of evolving oxygen, this apparatus being practically applicable for the use of nitrates, or chlorates of soda or potash and other salts, which evolve oxygen gas when heated.

One method of conducting this process is to place beneath the molten iron a perforated case capable of bearing a high heat, and containing the nitrate of soda or other solid matter. The heat of the molten iron causes the nitrate to liberate oxygen, which forces its way through the perforations in the case, and it issues into and amongst the particles of the molten iron, as when air is forced through the tuyeres in the ordinary way of conducting the Bessemer process. Mr. Bessemer's specification says : It is advantageous to use a converting vessel like that which is usually employed. I replace the tuyere box by a case of chamber lined with refractory material, and filled with the nitrate of soda or other material capable of evolving oxygen, and closed at the top with a perforated firetile. I make the case of such dimensions that the area of the surface of the nitrate is but small as compared with the area of the principal horizontal section of the metal in the converting vessel. In this way I both modify the intensity of the action and also prevent the rapid scoring action which would result from the passage of the gas between the metal and the sides of the vessel. Also in order to render the action more regular I fuse the nitrate and cast it into the case or chamber, and there allow it to solidify. The melted metal is then effectually prevented from acting on more than the upper surface of the cast block of nitrate ; or in some cases I mould the nitrate into blocks under heavy pressure before inserting it into the case or chamber, and the violence of the action of the nitrate may be reduced by mixing dry clay or other inert matter with it.

The invention also provides a means of forcing fluid nitrates into the converter, through the openings in a small central tuyere placed at the bottom of the converter instead of the ordinary tuyere box. A case containing the nitrate is attached to the converter and surrounded with an annular case. Into this annular case air or steam heated sufficiently to keep the nitrate fused, is forced by a pipe from the hollow trunnion in the ordinary manner. Below the chamber containing the nitrate, is a 4-way cock arranged to let air from the trunnion to the tuyere, for the purpose of heating the converter as usual, and also for the purpose of keeping the fluid iron out of the tuyere when the converter is turned up to blow, and the tuyere is thus brought beneath the fluid iron. By turning this 4-way cock when the converter is up, the air from the trunnion is shut off from the converter, and at the same instant let into the chamber containing the nitrate, while through the other passage in the 4-way cock, the bottom of the chamber containing the nitrate is connected with the pipe leading to the tuyere. Thus by the operation of turning the cock, air is shut off from the tuyere and nitrate forced into it, and thus into the molten iron in the converter, where the conversion proceeds in the ordinary manner.

A still later apparatus, patented by Mr. Bessemer, is illustrated in "Engineering," Nov. 13. The plan consists in forcing or injecting into molten crude iron streams or jets of fused fluid nitrate of soda or nitrate of potash; the streams or jets of fused or fluid matters are projected downwards at any desired angle from nozzles or tuyeres, the orifices of which are situated above the mean level or upper surface of the fluid iron to be operated upon, a portion of the said fused or fluid matters, as well as a portion of the cinder or oxides produced in the process, being again carried down into the molten metal as an induced current caused by the passage of the jets.

The process may be carried on in the ordinary converter, or in the hearth of a finery furnace. When employing such a furnace, Mr. Bessemer arranges a set of air tuyeres along one side for melting the pig metal and partially refining it; and on the other side of the hearth he employs a separate set of tuyeres or nozzles for the purpose of injecting the aforesaid fused or fluid matters into the molten iron. The process in this finery furnace may be discontinued while the metal is in the condition of highly refined cast-iron approaching to steel, or it may be continued until a more or less perfectly malleable metal is obtained suitable for melting in crucibles, or otherwise to form steel, or the metal may be allowed to granulate or assume a more or less solid condition, with or without manipulation with an iron bar or rabble, and be removed from the finery furnace in a condition to be formed into bars or blooms. The process may also be carried on in a reverberatory or puddling furnace heated by solid fuel, or by means of heated air and gas.

In carrying out the above process Mr. Bessemer prefers to melt the nitrate of soda, nitrate of potash, or other fusible matters in a jacketted iron vessel by means of highly-heated atmospheric air or superheated steam, and to use the pressure of such air or steam to act on the surface of the fluid matters, in order that they may thus be driven downward upon the fluid metal with such forceas to penetrate far into the molten mass, and put the latter into rapid motion, and thus in turn bring all parts under operation. This motion in cylindrical vessels is best attained by placing the jet pipes at a tangent to the circumference.

RAILWAY NOTES.

Railway Progress in the United States.—In 1865, the first 40 miles of the Union Pacific Railroad were laid; in 1866 there were constructed 265 miles; in 1867 a further length of 245 miles, and to November 1, in 1868, there had been constructed 330 miles, or, in 4 years, 880 miles. The total length of the road is 1,657 miles. The Central Pacific, notwithstanding the intervention of the Sierra Nevada, has progressed with equal rapidity; and the Union Pacific (E. D.) was, November 1, in operation from Kansas City to Sheridan, 405 miles. Railroad construction in the States east of the Mississippi and west of Pennsylvania has been during this period as follows:

———	Miles of Road.		
	1864.	1868.	Incr.
Iowa	800	1,680	830
Missouri	920	1,200	280
Minnesota	160	560	400
Wisconsin	1,050	1,200	150
Illinois	3,100	3,400	300
Michigan	870	1,260	390
Indiana	2,200	2,600	400
Ohio	3,200	3,340	140
Total	12,300	15,110	2,890

Thus in these 8 States in 4 years nearly 3,000 miles of new railroad have been laid and millions of dollars expended, not only on these, but also in improving previously existing lines. The total increase in cost has been nearly $200,000,000, or about $15 per head of the population.

Among the principal railroads in progress, or constructed in the four years referred to, the following are the most important:

In Iowa: the Iowa division of the Chicago and Northwestern, the Iowa division of the Chicago, Rock Island, and Pacific, the Burlington and Missouri River, the Sioux City and Pacific, and the St. Joseph and Council Bluffs. By the time that the Pacific Railroad is completed, the Rock Island and Burlington lines will have reached the Missouri.

In Missouri: the Pacific of Missouri, and the extensions of the North Missouri towards Iowa and the Missouri River. The Southern Pacific is also being extended southwest, and the St. Louis and Iron Mountain south, the latter to a connection with the Southern railroads at Columbus, Ky. The St. Joseph and Council Bluffs Railroad has also been completed to a connection with the Iowa Railroad of the same name, giving St. Louis an indirect route to Omaha. Several other roads are projected to connect with the Union Pacific Railroads.

In Minnesota: the Milwaukee and St. Paul, the Winona and St. Peter, and the Minnesota Valley. Considerable progress has also been made in the first division of the Pacific Railroad and its branch north to Watab has been opened through.

In Illinois: the St. Louis, Jacksonville, and Chicago, which gives another connection to the Illinois Central. The Rockford, Rock Island, and St. Louis is now in course of construction, chiefly as a mineral road, and designed to supply coal to railroads, etc. The St. Louis, Vandalia, and Terre Haute, and the Cairo, Mound City, and Vincennes are also in progress, with a view to their early completion.

In Michigan: the Jackson, Lansing, and Saginaw, and the Flint and Pere Marquette, are the principal new constructions. There is also being constructed a more direct line between Port Huron and Chicago, known as the Air-line. The Grand River Valley Railroad is approaching completion.

In Indiana: the Columbus and Indiana Central Railroad has completed a line from Union City to Logansport, and consolidated into itself the Chicago and Great Eastern, the Indiana Central and the Logansport and Burlington. There is also being built a line from Indianapolis to Vincennes to connect with the road to Mound City and Cairo; and several other lines are projected.

And in Ohio: several short lines, chiefly auxiliaries of existing lines. In this State several important consolidations have been effected.

Further east the principal developments have been rather improvements than new works. In New York the Erie is having a third rail laid to accommodate the narrow cars. The Hudson River has completed its second track, etc. The lines in progress from the Hudson have chiefly a northwestern direction, and will connect with the Central, the Midland being the most important. In a few years the Boston, Hartford, and Erie, will continue the Erie Railway to Boston. In the city of New York the depot and warehouse accommodation has been largely extended. In Pennsylvania, especially in the eastern portion, the extension of roads is being rapidly carried on, the objective points being Easton, on the Delaware, and New York city. In the southwest of the State the construction of the Pittsburg and Connellsville Railroad to a connection with the Baltimore and Ohio is being carried on actively. New Jersey has also made extensive improvements in its railroads and accommodations for an increasing traffic. The works at Hoboken, Jersey City, Communipaw, and Elizabethport are among the most extensive in the United States. In the Delaware peninsula railroad building is very active; and Maryland is connecting Baltimore more firmly with both East and West.—*Hunt's Merchants' Magazine.*

Irish Railways.—The total completed length of railways in Ireland is 1,908¼ miles of which there are 1,408 miles of single track, and 500¼ miles of double line. The length of railways in hand, and not yet finished, is 252 miles, and 339¼ are authorized, but not yet commenced. Of the first, the principal are the Great Southern and Western line, with a length of 165½ miles, and 253¼ miles of branches, connecting Cork with Dublin; the Great Northern and Western, 82¾ miles long, starting from Westport and ending with a junction at Athlone, with a short branch connected with the Great Southern and Western; the Midland Great Western, crossing the island from Galway to Dublin, with a length of 126½ miles of main lines and 120 miles of branches; and the Dublin, Wicklow, and Wexford Railway, with 98½ miles of main and branch lines.

On all these railways the bridge rail is the section principally employed, the mileage of flat-footed permanent way being 712¾; of double-headed rails 308; and bridge rails 1,750¼, which, together with 37 miles of various other sections, make a total of 2,408½ miles. The bridge section is, however, being abandoned, as is evidenced by the fact that only 6 of the different railway companies are adopting them for the permanent way renewals. The Great Southern and Western, who have hitherto employed rails weighing 80 and 90 pounds to the yard (the heaviest section in Ireland), are now replacing them with flat-footed rails. 26 other railways are following the example, while 6 companies are again employing the double-headed line.

Hoosic Tunnel Notes.—The work under the old contract has practically ceased, and it will not be renewed until a contract such as the last Legislature provided for is made and accepted by the Governor. The "Springfield Republican" says: We believe that the faith and hope in which the good people of the State have carried on the work, is fast breaking down. The tide is turning against the expenditure of any more of the people's money in that work. They say, "If it can be done, why will not the Fitchburg and the Vermont and Massachusetts railroads, which will most profit by it, and eventually will own it—why will not these corporations undertake the job and spend their own money in it? If they won't, we won't."

The condition of the work is as follows: On the east side the penetration reaches 1 mile through solid granite; the full-sized tunnel less than ½ a mile. The central shaft is sunk about 600 feet, and has 400 more to go. It is elliptical, 27 × 15 feet. On the west side the tunnel reaches 700 feet through quicksand and rotten stone, and is lined with brick. The west shaft is done, and the tunnel is driven from it 1,500 feet to the east, and 1,000 feet to the west. The entire length of the tunnel will be 4¾ miles, of which 3 are yet to be excavated.

Michigan Car Works.—The buildings of the Company at Detroit cover 4 acres. The specialty is freight cars. The number of hands is 150; the capital $100,000.

Railway Construction.—The following bits of high science are from a series of articles in a London technical paper. Speaking of sleepers: In America that kind of pine known as "Hemlock," or "Hemlock Spruce," has been found the best, although with such a choice of timber, white oak, chestnut, and all sorts of wood are used. Sleepers must always be straight, and of an uniform size, for otherwise the bearing or rather the running, would be commensurately imperfect, or "poor," as it is called. As to improved rails: Rails should be made of puddled iron, that is, iron into which atmospheric air has been introduced by stirring or "puddling" with a rod whilst in a soft state. We most of us know the mode of annealing, or rendering brittle iron wire soft, so that it will bend without breaking—namely, by heating and allowing it to cool—in other words, exposing it when hot to the air. This is a simple thing enough, and the principle upon which it is done forms the basis of Bessemer's steel. (!)

Electric Repeaters for Railway Signals.—On several of the English railways, the proper condition and working of distant signals is made known to the signalman in the station by electric "repeaters." By means of a very simple arrangement—1st, the raising or lowering of the signal makes or breaks a circuit which shows or repeats the same operation on a model of the signal in the station. If the wire or other apparatus leading from the station to the signal is out of order or fails to work from any cause, the model also fails to work, and the danger is at once discovered; 2d, at night, the light in the signal is arranged to heat a piece of iron above it. If the light goes out, the piece of iron cools, contracts, and so breaks a circuit which at once covers up or puts out a corresponding light in the signal station. A similar apparatus could be well, and in the long run economically applied to testing the condition of switches where trains have to pass them at speed.

Railroad Track-Layer.—This machine is said to have laid from 1 to 2 miles of track in 12 hours on the Vallijo and Sacramento Railway. The contractor is of the opinion that it may be so improved as to lay 5 or 6 miles per day—or 12 times as fast as by hand.

The machine is a car 60 feet long and 10 wide. It has a small engine on board for handling the ties and rails. The ties are carried on a common freight car behind, and conveyed by an endless chain over the top of the machine, laid down in their places on the track, and when enough are laid a rail is put down on each side in proper position, and spiked down. The track-layer then advances, and keeps on its work until the load of ties and rails is exhausted, when other car-loads are brought. The machine is driven ahead by a locomotive, and the work is done so rapidly that 60 men are required to wait on it.

Bridging the Connecticut River.—Messrs. A. D. Briggs & Co., of Springfield, Mass., have made a contract with the Shore Line Railway Company to build the drawbridge across the Connecticut River at Lyme. The bridge is to consist of 5 spans of 175 feet each, 3 of which will be east of the draw and 2 west. The length of the draw is to be 275 feet, and allowing 35 feet for the central pier leaves 120 feet clear. The piers are to be made of cast-iron cylinders, each cylinder to be driven over a cluster of 12 piles, and the interstice filled with concrete. The draw is to be of iron, and the rest of the bridge will be constructed on the Howe plan. The cost of the whole structure will be about $200,000.—*Railway Times.*

Ohio Bridge at Louisville.—The iron railway bridge now in course of construction between Louisville, Ky., and Jeffersonville, Ind., will be just 1 mile in length. It will have 24 spans; 2 of these will be 370 feet each, and 6, 245.5 feet each. Excepting on the longest spans, the rails will be placed on the tops of the girders, these being of the class known as the Fink truss. The estimated cost of this bridge, which is to be completed by September 1, 1869, is $1,600,000. The chief engineer of the work is Mr. Albert Fink, and the assistant engineer, Mr. F. W. Vaughan.

Chicago River Tunnel.—This work is approaching completion, and is to be opened in the spring; cost $500,000.

PEAT FOR LOCOMOTIVE FUEL.—The following is the report of a commission sent out by English capitalists to test the value of peat as a fuel for the purposes of running the Grand Trunk Railway in Canada:

Number of miles run by train....	683
Aggregate distance run by all the cars	15,267
Average number of cars per train	22.4
Peat consumed, in pounds......	48,475
Wood, in pounds, for same work	105,187
Number of miles run per ton of peat	31.6
Number of miles run per cord maple wood	27.6

Experiment in favor of peat, 14 per cent.

A RAILROAD QUESTION.—The Grand Trunk Railroad being in a state of complete wreck, owing to the miserable mismanagement and corruption that has prevailed in its direction, the question is whether the railway commissioners, 3 in number, who are appointed by the State to make frequent inspections of the track and of the service of the railways, and to report all defects and abuses to the proper authority, are liable criminally on indictment for murder, as accessories before the fact, should death result from the running of trains over roads left in such a condition by their negligence.—*Springfield Republican.*

AN UNDERGROUND RAILWAY IN PARIS is to be built, more with the view of bringing in market produce from the suburbs than for the purposes of passenger traffic. It is to start from the Halles Centrales, at the extreme end of the Rue St. Honoré, and take the line of the quays as far as St. Cloud, whence it will proceed to La Marche, famous for its steeplechases, where an immense station is to be constructed, which will form the starting point of a new circular railway passing entirely round Paris at several miles distance.—*Railway News.*

SINGULAR RAILWAY ACCIDENT.—A 1,600 feet tunnel on the Marietta and Cincinnati road, caved very badly during excavation, and was filled in, over the arch, with 8,000 cords of wood (!), which recently took fire, burned the stone to lime, and filled up a great part of the tunnel.

THE GAUGE QUESTION.—The laying of a third rail for narrow gauge trains, throughout the length of the Erie road, is said to be decided upon. Engineers long since estimated that the saving of expenses on the narrow gauge, would, in say 30 years, pay for the change of track and equipment. But it is possible that the introduction of steel rails will enable the wide cars to carry weight in proportion to their width without injury to the permanent way, and that the railway of the future will be wider than 4 feet 8½ inches.

NEW RAILROADS IN GEORGIA.—State aid having been granted, the "air line" road from Atlanta to Charlotte, N. C. (traversing the gold belt), is likely to be built. The Northeastern road, connecting Atlanta (and Augusta) with the Tennessee roads, is also being pushed forward. The Macon and Brunswick road is nearly completed. Branches of the Southwestern, through the fine cotton region, are also in progress.

NEW RAILWAY ACROSS EGYPT.—The new route by rail from Alexandria to Suez, by way of Zagazig, was opened in October. The former route by rail was from Cairo to Suez, the distance from Alexandria to Cairo being traversed by canal and the Nile, or by rail; but this making a considerable detour, and lengthening the journey. The entire length of the new route is 85 miles.

INSURANCE TICKETS.—As long as cars are warmed by coal stoves, and combustibles are mixed up with general merchandise, passengers should provide themselves with stamped and directed envelopes, buy insurance tickets at stations, and post them to their friends before consigning themselves to etc., etc. Otherwise their evidence of insurance will be burned up with them.

PENNSYLVANIA RAILROAD MANAGEMENT.—"The watchful forethought which provides for every emergency, and the energy with which all works essential to the accommodation of the public on this road are prosecuted," is the just comment of the "Railway Times" on the rebuilding of 5 spans of the Harrisburg bridge in 12 days.

Quadruple Tracks.—The Midland Railway has 4 lines of rails from London to Bedford. The North-Western has 3 lines for 46 miles out of London, and the Great Northern will soon have 3 lines for 22 miles.

The New Haven and Northampton R. R. Co. at the expiration of its lease to the New York and New Haven, in June, 1869, will equip it with new material throughout, and will extend the Collinsville branch to New Hartford.

OBSERVATIONS ON THE WOOLF ENGINES

RECENTLY INTRODUCED INTO THE FRENCH NAVY.

BY VICE-ADMIRAL LABROUSSE.

Translated from Annales du Génie Civil.

Note by the Editor of "Annales du Génie Civil."—A question of great importance is agitated in the Special Commissions of the Marine; that is, the adoption of a better type of engine for the vessels of the fleet. This question also touches so very nearly the interests of the commercial marine, and the great works for the construction of steam engines, that we cannot neglect this occasion to make known to our readers the different opinions held by men whose opinions and works have greatly contributed to place our marine in the first rank.

We repel the idea that in such grave circumstances, in which it is proposed to render general a system, good or bad, which involves the outlay of many millions, personal influence can prevail, and an erroneous system be adopted, because it comes from a high quarter, with the prestige of a name that generally is accepted as a guaranty of truth. To abandon frankly a theory when facts demonstrate that it does not realize the results expected from it, is a rule of conduct among engineers who are ambitious to achieve real progress rather than momentary celebrity. The real progress is generally attained by experience gained in contending with the practical difficulties that are met in attempting to carry out theories.

In publishing (April, 1867) the paper read before the Academy of Sciences by Mons. Dupuy de Lôme, and in publishing now that by Vice-Admiral Labrousse, we give our readers the means to form a clear opinion of the two systems which are placed in competition. We think, with the majority of competent judges interested in the question, that the Woolf system, applied to marine engines, has no advantages, and many inconveniences; and, without adopting the violent criticisms which the English engineer Burgh has made on the engines of the "Friedland," in the "Engineer" of August 23, 1867, we think that the paper of Admiral Labrousse, by its numerical results, sustains the conclusions of Burgh.

The "Friedland's" engine has three cylinders operating on cranks 90° and 135° apart. In the middle cylinder the steam is at full pressure, for .8 of stroke, and is then cut off. It is exhausted into the two other cylinders of the same size; and when released from them into the condenser, it has double its initial volume, and half its initial pressure. The cylinders are 84 inches diameter and 52 inches stroke, and work at 56 turns per minute; and the mean pressure in the high-pressure cylinder is computed at 33 inches of mercury.

Observations of Admiral Labrousse.—Several journals have published a note of Mons. Dupuy de Lôme on the engines with 3 equal-sized cylinders, with steam direct from the boiler admitted into only 1 of them, which note had been communicated by him to the Academy of Sciences. Though that note contains, on several essential points, and even principles, assertions in which we think there are grave errors, we should abstain from examining it critically if the question had not a serious importance in relation to our naval material, and the precedents it might establish were not likely to be too much relied upon.

In July, 1863, a commission, composed of Vice-Admiral Labrousse, president; Mons. Sabattier, engineer of the marine; Mons. Guesnet, sub-engineer of the marine; and Mons. Testard du Cosquer, lieutenant, was directed to make comparative experiments on the engine with 3 cylinders, and on the ordinary engine with 2 cylinders.

These experiments had great interest; for it was desired to know whether to commit the imperial marine definitely to the 3-cylinder system, as applied in the Friedland, or 3 cylinders acting independently; or to adopt in 2 other frigates then in progress, ordinary 2-cylinder engines of equal power.

The duration of each experiment was 12 hours. Dispositions were made to work the engines either in the way for which they were constructed, with steam admitted directly into only 1 cylinder, or in the ordinary way. In the latter case, the ports of the middle cylinder were stopped, and the valve removed, so that the steam could go directly to the outside cylinders after passing through the valve-chest of the middle cylinder. The engine was thus transformed into an ordinary 2-cylinder engine, but with some disadvantages attendant. 1st, that the steam on its way to the cylinders had to circulate in the pipes and valve-chest of the middle cylinder; 2d, that they had to work 2 cranks set 120° apart, instead of 90°. The experiments were made alternately, with the machine in its normal condition, and thus transformed. All precautions suggested by experience were taken to arrive at results as minutely exact as possible.

The general result of the trials was an economy of 3 per cent. of the fuel in favor of the new system. But in the 2 last trials which the commission deemed more comparable between themselves, this economy rose to 7 per cent.

Being directed to express its opinion on the comparative utility of the 2 machines for use in war vessels, the commission, after balancing their advantages, decided in favor of the 3 cylinders. But, notwithstanding the saving of 7 per cent. of the fuel, they advise that in the 2 vessels of 1,000 horse power about to be engined, the 3 cylinders should be arranged to work independently, but capable of rearrangement to work on the Woolf system, if new experiments on a larger scale should show farther advantages in that system.

In consequence of that advice the engines of the Gauloise and the Revanche have been constructed with 3 independent cylinders, with provisions for making the change suggested.

The note cited presenting, as an important progress, the use of "engines with 3 equal cylinders with steam admitted directly into only 1," of which the engine of the Loiret presents the first specimen, there may be a disposition to conclude that the commission has erred in its appreciations; and that in recommending engines with 3 cylinders of the type of the Gauloise in preference to those of the type of the Loiret and Savoie, it might lead the administration of the marine into a way that would be regretted.

Now, there is no danger of this. The last comparative experiments made under the same conditions, between the engines of the type of the Magnanime and the Savoie, and those of the Gauloise type, proved incontestably the superiority of the latter; and, consequently, fully confirmed the conclusions of the commission. As will be seen, that proof is easy to be apprehended, and will not escape those who have opportunity to judge of it. To render it more clear, we will follow step by step the author of the note, in the parallel which he draws between his engine and that with 2 cylinders.

The advantages which he claims in favor of the 3-cylinder system are: 1st, economy of fuel; 2d, the faculty to increase the number of turns that may be given to the screw without gearing; 3d, the almost complete balance of the movable parts around the shaft, whatever may be the position of the vessel in rolling. We propose to demonstrate that, compared with the 2-cylinder engine, these advantages are null, or much exaggerated; and that compared with the engine with 3 cylinders independent, the new machine, derived from the system of Woolf, is far inferior in all respects, except that of economy of fuel, in which they are sensibly equal.

1. *Economy of Fuel.*—The note estimates at 20 per cent. the economy of fuel which the new engines realize over the 2-cylinder engines. This is a mere hypothesis, which, thus far, is not confirmed by facts. In reality, if we recur to the experiments on the Loiret, which, on account of their great number and duration, are entitled to confidence, the mere economy of the new engine over the old one is but 3 per cent., and in the case most favorable for it is but 7.2 per cent. And we must further remark that the 2-cylinder engine on which the experiments were made was that of the Loiret, temporarily transformed for the purpose; and that it presented, as we have already said, in respect to the working of the steam, a

certain inferiority to the ordinary 2-cylinder engine, because of the unusual circuit the steam had to make on its way to the cylinders, and because of the irregular working.

Actually, if we compare the new system with that of the 3 independent cylinders, it will suffice to assure us that they are sensibly equal in economy of fuel, to look at the following table, which shows the results of the experiments recently made under full steam by the frigates. The Magnanime, the Savoie, and the Valeureuse have engines on the new system of Mons. Dupuy de Lôme; and the Revanche and Gauloise have engines with 3 independent cylinders:

Names of Vessels.	Gauloise.	Revanche.	Magnanime.	Savoie.	Valeureuse.
Names of Engine-builders.	Mazeline.	Forges at Chantiers.	Mazeline.	Forges at Chantiers.	Indret.
Date of Trials.	August 2, 1867.	July 25, 1867, Mean of Trials.	June 26, and July 24, 1866.	May 17, 1866.	August 26 and 31, 1867.
Pressure in inches	32.2	26.8	59.6 and 56.4	60	54
Saturation	2.57°	2.57°	2.43°	2.43°	2.42
Fuel per horse-power per hour, kilog.	1.371	1.515	1.295 and 1.285	1.622	1.409
Total horse-power	3,639	2,554	3,506 and 3,326	3,197	3,467
Number of turns	56.3	52	54.86 and 54	54.1	55.4

The consequences derivable from these figures are : 1st. If we compare together the engines built by the works of the Forges et Chantiers, we see that the Revanche, working with 3 cylinders independent, has an advantage of 6.6 per cent. over the Savoie, with the new arrangement. The Gauloise and Magnanime, by Mazeline, the advantage is 6 per cent. in favor of the new arrangement. 2d. Comparing the mean consumption of the 3 new engines with that of the 2 ordinary ones, we find 1 per cent. in favor of the former. From these we may conclude that the 2 types are sensibly equal in economy of fuel, under the conditions in which they were tried. But it should be observed that in the ordinary engines one source of economy was neglected ; since the same degrees of saturation were maintained as in the others, though the pressures averaged 28 inches lower. If the blowing-off had been proportioned to the pressure, there would assuredly have been an economy of at least 4 per cent. in favor of the old system.

We will add that, for the greater number of competent men, it is no longer doubtful that with an ordinary engine, conveniently disposed, we can obtain results as economical as with the Woolf engines.

Further : these engines were not steam-jacketed. That of the Friedland, which was the subject of Mons. Dupuy de Lôme's note, was steam-jacketed ; and on this addition, and some other dispositions, the author founded his hopes of a notable advantage in favor of his new system. As these favorable additions and dispositions are applicable to the old system, it is clear that this system can derive an equal benefit from them ; and that, consequently, they cannot affect the relative economy of the two systems.

In sum, we must consider the two systems as having shown equal economy of fuel ; and there is no appearance of that economy of 20 per cent. in fuel, which is the question in the note we have to examine. And we doubt if even this economy, were it realized, would compensate for the notable disadvantages of the new engines, as compared with ordinary engines.

Another important fact appears from the figures in the preceding table ; it is, that for pressures as high as 54 to 60 inches in the new engines, working with full steam, the power varies from 3,467 to 3,506 horses, while those of the Gauloise with only 33.2 inches, and cutting off at .4, develop a power of 3,639 horses. This power was raised even to 3,886 horses during three consecutive observations out of the nine which were made during an experiment of 6 hours and 20 minutes; the pressure then rising to 36 inches. And the Savoie, with 60 inches, developed only 3,197 horses power, while the Revanche, with only 26.8 inches pressure, developed 2,554 horses power. Hence it appears that when the new engines work at the normal and prescribed pressure of 53 inches, and no longer at that of 60, used in the experiment, they will develop a power notably less than 3,500 horses, whatever may be the energy of the fires and the production of steam; because in the trials the admission of steam was at its maximum.

On the contrary, in the ordinary engine, the power, which was kept at nearly 3,900 horses during part of the experiments, could be raised much higher without augmenting the pressure, were the production of steam sufficient to admit it during .65 of the stroke, instead of only .4, at which they then worked.

The ordinary engine, with three independent cylinders, has then, in this respect, a considerable advantage over that on the system of Woolf; for the power of this, inferior to what it ought to be, cannot be augmented except by an increase of the speed of movement, which is already excessive; while the speed of the ordinary engine, without diminishing its power, may be notably reduced by lengthening the pitch of the screw, accompanied either by an increase of pressure, or by a longer admission of steam, the pressure remaining the same, without sensible loss. The pitch, for example, could be 28.3 feet, the same as heretofore adopted for engines of this power.

In other points of view, the speed of movement, which is required to be greater in the engines on the new system than in that to which the engines of the Gauloise may be reduced for a given power, as we have explained, increases the chances of derangements in the machinery so much the more by requiring a higher pressure and temperature; so that there is a constraint to run faster, when, on the contrary, there should be less speed than in the ordinary engine, to insure equal safety. This is a grave inconvenience.

While saline incrustations present, in their formation, irregularities which are unexplained, experience proves that we cannot without danger employ pressures so high as 54 inches. In fact, in the Loiret, with 50 inches mean pressure, copious blowing-off did not suffice to keep the boiler free from incrustations, which in 96 hours of firing attained to a .4 of an inch thickness, although care was constantly taken to keep the salinometer (saturomètre) under the regulation figure of 3°. It was therefore indispensable that the new engines should be provided with surface condensers, in order that the high pressures they require should be admissible; and that condition was pointed out in 1863 by the president of the commission, for cases in which this kind of engine was persisted in.

Finally, we must foresee the time when boilers will be more or less weakened by use, and it will be necessary to lessen the pressure on the safety-valves, and work with lower pressure. In the new engines, which, even with the normal pressure of 54 inches, do not develop the power desired, there will be a diminution of power corresponding to the diminution of pressure, while in the Gauloise engines there will be the capability of maintaining full power, even with the low pressures, by allowing the steam to follow as far as may be necessary.

2. *Capability of increasing the number of turns of screws that can be obtained without gearing.*—To prove this capability, M. Dupuy de Lôme depends on the assumption that while the effectiveinitial pressures in his engine is 38.4 inches, that in the 2-cylinder engine must be 75.2 inches. Without examining at this moment whether the initial effective pressure will be under all circumstances 38.4 inches in the new engines, it is easy to see that the author commits a manifest error in estimating at 75.2 inches the pressure in the 2-cylinder engine working under the conditions indicated. In effect, this is his reasoning: "With an engine with 2 cylinders equal in diameter and length to those of the 3-cylinder engine, and making the same number of turns, it would be necessary to increase the mean pressure in the ratio of

3 to 2 : it would then be 50.4 inches instead of 33.6. But to obtain this mean pressure of 50.4, even with an admission of .7, and a back pressure of 4 inches, it would be necessary that the initial pressure should be 79.2, giving 75.2 inches effective pressure."

The first of these assertions is very exact; but the second is absolutely inadmissible. It is true that the mean pressure ought to be 50.4 instead of 38.4 inches; but it is easy to see by the diagram, that to obtain a mean pressure of 50.4 with an initial pressure of 79.2, it would be necessary that the line of pressures should assume a special curve, which could not be produced except on the double condition of close throttling and cutting off at .2 or .3 of the stroke. In the case we are discussing, cutting off at .7, we are far from this last hypothesis.

As to throttling, we need not have recourse to it: for it is too generally admitted, contrary to an opinion that has long prevailed in the marine, and that the author of the note seems still to hold, that throttling is disadvantageous, since even in the condition in which he places it, the loss of power by it would not be less than 10 per cent. And to get a mean pressure of 50.4, the boiler pressure would be raised, not to 83.6, but only to the point necessary to get the mean pressure proposed, with the valves wide open, as has usually been the practice; and in that case we should have a diagram of the usual form. Under these conditions it will be seen that for a mean pressure of 50.4 the maximum will be 56 inches in the cylinders, and about 34.8 in the boilers above the atmospheric pressure.

In what concerns the engine with 3 independent cylinders, the maximum pressure according to the diagrams would be 54 for a mean pressure of 33.1 inches. And, even according to this mode of computation, the maximum pressures in the 2-cylinder engines would exceed that in the new engines by only 17.2 inches instead of 36.8, as assumed in the note, and by only 14.8 inches in the engines with 3 independent cylinders, an excess that could easily be made to disappear, as we have before shown.

But this mode of computation is absolutely inadmissible, because it takes no account of the inertia of the reciprocating parts. In effect, during the first half of the stroke, the pressure on the joints of the connecting-rod is equal to that on the piston, minus what is necessary to give to the reciprocating parts the speed required by the movement of the crank. During the last half, on the contrary, the pressure is equal to that on the piston, plus what is necessary to extinguish the speed, or the *vis viva* generated during the first half of the stroke.

Calculations of all the particulars of this nature involved in the three types of engines, show that the new engine has an advantage of only 10 per cent. over the 2-cylinder engine; that is, in the ordinary 2-cylinder engine the maximum pressure is only 10 per cent. greater than in the new engine; and in the engine with 3 independent cylinders the maximum pressure is a third less than in the new engine. These consequences singularly attenuate the importance which the author hopes to draw in favor of his new engines, from the consideration of the more equable pressure on the gudgeons and crank-pins, as compared with the ordinary 2-cylinder engine; and they show, in this respect, a great advantage in favor of the engine with 3 independent cylinders—a double result which appears not to have been foreseen.

3. *Static Equilibrium.*—The third advantage claimed by the author in favor of the new engine is, "the almost complete static equilibrium of the moving parts around the shaft."

This assertion is evidently exaggerated, for the fixing of the 3 cranks at 90° and 135° distance affects notably (in the ratio of 1 to 1.4) the static equilibrium in question. If, in this respect, we compare the engine of the Friedland with 2-cylinder engines, which are counterweighted, as in the practice of Mazeline and Indret, it is easy to see that the latter are in the best condition of static equilibrium; and that if one them had been set up in the Champ de Mars in the same manner as that of the Friedland, it would have shown results superior in this respect.

As to the engines with 3 independent cylinders, they also are manifestly in the best condition of static equilibrium, since their cranks are fixed exactly at 120°.

Finally, if we consider the variations of the *couples of rotation*, it will appear, from the curves which represent them, that there is a considerable advantage in favor of the engine with 3 independent cylinders; and a less but still notable advantage in favor of the 2-cylinder engine. In effect, the ratio of the minimum to the maximum power during the revolution is: for the 3 independent cylinders, 1 to 1.4; for the 2 cylinders, 1 to 1.74; and for the new engine 1 to 2.56.

The fixing the cranks at 90° and 135° has more serious consequences than might be supposed. We have said that it alters in the ratio of 1 to 1.4, the conditions of the static equilibrium. An examination of the curves of rotation will show the pernicious influence which it exercises in this new point of view.

Conclusions.—Comparing the new engine, derived from the system of Woolf, with the common 2-cylinder engine, we see, from what has been shown, that the latter (placed in conditions exceptionally disadvantageous, as it was in the Loiret) consumes from 3 to 7 per cent. more fuel; a small inconvenience in itself, which is more than compensated in a war vessel by the advantage of employing for the same number of turns of the screw, a much lower pressure in the boiler, and consequently a lessened liability to incrustations—so rapid at high temperatures, and a lessened danger of eventual rupture of the boiler; or, if it be preferred to use the same pressure, a slower rotation of the screw may be adopted.

The maximum stress on the gudgeons and crank journals are greater in the 2-cylinder engine; but are not double, as the author of the note claims; and the difference, 10 per cent., is at most insignificant.

In compensation, the uniformity of the couple of rotations is more satisfactory in the 2-cylinder engine, and this engine costs less, weighs less, and occupies less room; and herein (besides the lower boiler pressure) is an important military advantage, since the excessive thickness of the armor plates now used puts great difficulties in the way of the effective armoring of the vital parts of war vessels.

Finally, since the normal pressures in the boilers are very unequal in the two engines, for a given power, it follows that when the boilers have become weak, and it is required to lower the pressure, conformably to the rules in force, that reduction will be much more disadvantageous in the new than in the old engine; for the power of the new engine will decline with the pressure, while that of the old one will remain undiminished though the pressure be greatly reduced.

After balancing their respective advantages and inconveniences, it appears that the superiority attributed to the new machine by its author, over that with 2 cylinders, is entirely contestable. But compared with the 3-cylinder engines of the Gauloise type, the new type of the Savoie falls short in all respects. In effect: 1st. They are equal in economy of fuel, nevertheless, with 23.6 inches lower pressure, the Gauloise engines have realized 400 horse power more. 2d. They offer more security in running the screw at higher speed, because the couple of rotation is more regular, and the stress on the journals is 50 per cent. less, and the strains that may arise from elevation of the temperature of the steam are less to be feared. 3d. The static equilibrium of the reciprocating parts is more complete, because of the more regular positions of the cranks on the shaft. 4th. To realize the normal power of 4,000 horses, we can in these engines reduce the speed of screw adopted in that of the Friedland, by increasing either the pressure (without exceeding the limit of 53.2 inches), or the admission of steam; while in the Friedland's engine it cannot be obtained without exceeding this pressure, or increasing the number of turns, already too great. 5th. As the normal admission in the Gauloise engines is but .4, when the boilers have become weakened, we can, without lessening the power, by cutting off later, use a lower pressure, which would be impossible in the new engines, where the admission is already at its maximum. 6th. Finally, in case of disabling one of the outside cylinders, the engine of the Friedland, in the condition in which it is worked, would be nearly in the predicament of a 2-cylinder engine with one cylinder disabled; while that of the Gauloise could disconnect either of its 3 cylinders without ceasing to be a well-connected engine.

To recapitulate: the 3 advantages which the author attributes to the new engine compared with the 2-cylinder engine—advantages which we have reduced to their just value in this case—are changed into many causes of marked inferiority when compared with the 3-cylinder engine of the Gauloise type; which possesses, moreover, the advantages of the first order stated in sentences 4 and 5 of the last paragraph. This machine, derived from the Woolf system, is therefore far from constituting an "important progress," as claimed in the *Note*. Its principal defects may pass unperceived in time of peace, because the occasions when it is necessary for the engines of war vessels to develop their full power will be rare and of short duration. But during war, for which these vessels are built, the rapid movements which require high pressure and hazardous speeds of piston will be frequently required and obtained; for the persons in charge will then very often be over-excited by sentiments which in time of peace have influence only in very rare cases of danger. Then will be revealed the serious dangers of these engines. In prospect of such eventualities, we should not hesitate to transform them without delay into engines of the Gauloise type, which, happily, can be done without difficulty. This type begins to increase in the English fleet (the type of the Octavia, by Maudslay); and the Commission of the Loiret, in recommending it in 1863, in preference to that which the *Note* sought to establish, indicated to the administration one of the best ways that it could follow. That is what we have endeavored to demonstrate here: and we hope we have done so by satisfactory evidence.

WOOD PAPER.—David Adam Fyfe, of Edinburgh, patents methods of preparing paper pulp from wood, etc. According to this plan the wood, reduced to thin shavings, and cut into suitable lengths, is boiled under a pressure of about 10 pounds per square inch, first with a solution of caustic soda, and afterwards with a weak solution of sulphuric acid. Next, the macerated shavings are subjected to a crushing or opening out process, and the fibre obtained is submitted to action of a washing and beating engine, the water used in this engine being rendered acid by the addition of about 1 part of sulphuric acid to each 30 parts of water. Finally, the fibre, whilst still saturated with acidulated water, is put into a bleaching engine charged with a solution of chloride of lime; and in some cases air forced in by a fan or pump is caused to pass up through the fibre whilst it traverses the race of the bleaching engine, thus facilitating the process of bleaching. The patent includes the apparatus to be employed in carrying out the above mode of treatment.

SHIP CANAL TO PARIS.—The "Revue Moderne," of Paris, opens up an old French idea, which was also a "Napoleonic idea"—that of making Paris a seaport by a canal to Rouen and Havre *via* the Seine. It was one of Vauban's projects, and it was encouraged by various monarchs. The present projectors say that large ocean steamers could reach Paris by canal, taking the freight at that city and the coal at Havre. It is proposed that government shall guarantee $4\frac{1}{2}$ per cent. to the Canal Company, and that the excess of the proceeds over 6 per cent. be kept down by reduced rates. Remarkably enough, the ancient blazon of the city of Paris is a ship. The quays of the Seine —the finest in the world—would seem to have been adapted in advance to that idea of a grand metropolitan canal, which would be one of the most arduous modern achievements in engineering.

WATERING ROADS.—A paper was read before the British Association on this subject, tracing the history of the practice from the time of throwing water from the gutters with a shovel, to the watering cart of the present day, which inadequately does the work in London, for instance, at the cost of half a million (gold) per summer. The paper states that 1 pound or $\frac{1}{2}$ pound of chloride of calcium and chloride of sodium mixed to 1 gallon of water, thrown into the watering cart, hardens and concretes the surface of a road to such an extent that no dust arises. Also that the saving of water is 75 per cent.; that the deliquescent salts are also antiputrescent; and that much cost of road repairs is saved.

CENTIGRADE TO FAHRENHEIT.—Multiply the centigrade degree by 2. Subtract one-tenth of the product from the product itself, and add 32 to the remainder. The result will be the Fahrenheit degree.

SEACOAST DEFENCES.

THE QUESTION OF MASONRY FORTS—MONCRIEFF'S SYSTEM OF PROTECTING GUNS.

The recent experiments on ordnance against armor at Fortress Monroe and at Fort Delaware have repeated the fact so often and so fully demonstrated at Shoeburyness, that adequate fixed iron defenses are *costly* to an extent that may, with our extensive coast line, absolutely prevent their general introduction. The experiments have also established other facts of importance to which farther reference will be made.

The experimental targets at Fortress Monroe were—*First*, an open embrasure of earth, strengthened by iron about the throat, designed as a modification of the barbette system, and intended for the protection of gunners and guns firing over earthen parapets. Mere earthen slopes would be too flat to afford any protection. An iron shield, with a notch in the top, forming an embrasure for the gun, was, therefore, set into the earthen embrasure. This shield was composed of solid plates 12 inches thick, supported at the back by 2 posts and a cross beam, each 12 by 15 inches in section, and embedded at the bottom and sides in an internal wall of masonry. Three spherical shots from the 13-inch gun, and one from the 15-inch gun, broke up the plates and the vertical beams very badly. The horizontal beam was not broken, but the internal walls and their iron clamps were shattered.

The more important experiment was upon a casemate having an iron front or shield. Instead of the ordinary wall pierced with an embrasure, the front of the work consisted of 2 heavy piers, one of stone and one of brick, 14 by 16 feet in plan, and 11 feet apart, this intervening space being closed with the iron shield pierced for the gun, and the covered casemate for the gun being formed of rear piers and arches in the usual manner. The shield was composed of two 12-inch plates about 4 feet wide on each side of the embrasure, each plate being supported by two 12 by 15-inch vertical iron posts in the rear. To close the bottom part of the opening between these plates, a 15-inch plate, made up of 2 thicknesses of 7½ inches each, was set up outside of them, forming the sill of the embrasure, and another narrow plate formed the lintel. The whole was secured by suitable bolts.

The shield presented an area of 11 by 12 feet, and received 6 shots at 150 yards range, viz.: 3 steel balls of 480 pounds, and one cast-iron ball of 450 pounds from the 15-inch smooth bore, the last 3 being with the maximum charge of 100 pounds of powder; and 2 shots from the 12-inch rifle, one of them a 658-pound steel bolt, with 70 pounds of powder, and the other a 658-pound chilled iron bolt with a 64 pound charge, representing 500 yards range. One of the shots struck a lintel over the embrasure, breaking it in two; the others struck in most instances upon the weakest parts of the shield, and without perforating the 12-inch plates threw off fragments from the rear of the plates, though to no great distance, and which would have been stopped by an inner skin. 2 of the iron posts, to which the armor plates were fastened, were broken clean across, and a third post in 2 places, the fragments being thrown down. Other shots were fired at the masonry with charges representing 1,000 to 500 yards range. The brick pier, at the close of the trial, was a mass of ruins outside, while the stone pier, though badly damaged on its face, showed no injury within that need seriously impair its defensive capacity. The most important damage to the stone pier was at the angle where it joined the iron shield, it having been struck by an oblique shot. If the shield had been built farther into the pier, this injury would, probably, have been less serious.

It is but just to General Barnard, who designed the work, to state that 3 years ago, when it was planned, no equally heavy armor had been destroyed by English ordnance, and our own heavy guns had not been tried with their present enormous charges.

The other experiments at Fortress Monroe were as follows: An embrasure planned by the late General Totten, consisting of the usual masonry with a throat of plates or bars 8 inches thick, received 8 shots from this heavy ordnance, and was badly shattered both without and within.

The experiments at Fort Delaware, December 3d, were designed to test another manner of strengthening an existing embrasure by iron armor. One of the Totten embrasures of the fort was opened out to a hole 8 feet wide by 6 feet high, and lined by 1-inch iron plates. Inside the opening was set up a solid 8-inch plate backed by a 7-inch plate made in 2 pieces. The 15-inch shield thus formed was pierced by a 3 by 4 feet embrasure cut out of the solid iron, with rounded corners, and was supported in the rear, at each side, by a bracket extending from the top to the bottom of the casemate, and built into the masonry. The bracket was made of vertical and horizontal 1-inch, and $1\frac{1}{2}$-inch plates riveted together like a compound girder.

A 624-pound chilled iron shot, with a 64-pound charge (representing 70 pounds at 500 yards range), was fired from the 12-inch rifle at 150 yards range, and 1,180 feet initial velocity, and drove a clean hole through the 15 inches of iron. The second shot, a 15-inch steel ball with 84 pounds of powder, shattered the rear of the shield, but did not penetrate. The third shot, a 15-inch cast-iron ball, did less damage, but knocked pieces off the rear of the shield. Three 15-inch balls and one 12-inch rifle shot were then fired at the masonry—the unbroken wall of the fort, which was found to stand better than the isolated masonry structures before mentioned. The 1-inch linings of the embrasure did good service in keeping out splinters. The box-bracket supports held on well, and proved, what has often been proved at Shoeburyness, that this is the best construction for backing and supporting shields. The plates, however, were very defective. They were rolled at Pittsburgh, from piles of $1\frac{1}{4}$-inch plates, out of iron considered good for machinery purposes, but evidently too hard for armor. The English experience long since proved that iron having the highest tensile strength, is unfit for resisting sudden blows, and that hard steel plates are quite worthless for this purpose. Hard plates are cracked like glass. Soft plates are bulged and distorted, but they *keep out the shot.* The plates referred to were also badly welded; this was shown by the complete separation of the $1\frac{1}{4}$-inch laminæ at the fracture.

The question then arises, can our coasts be protected by any other means than perpendicular walls of either iron or masonry? General Barnard says on this subject in a letter to the "New York Times": "I feel confident that every engineer would most gladly substitute earth for crumbling granite; far more gladly, indeed, than to resort to a material so costly as iron and, *as yet, so unsatisfactory.* Earth is the cheapest of all materials, and the best possible medium to resist cannon shot. Let any one, however, look at a 15-inch or a 20-inch gun mounted behind an earthen parapet, and he will recognize that those who load and direct these ponderous weapons *are scarcely protected at all*, and this defect is not remedied by forming an earthen embrasure. Unless, therefore, the battery be very high, earth *alone* is entirely inadequate as a protection for guns or gunners. Again, it frequently occurs that very limited but most important sites are to be occupied, such as the artificial sites at Spithead, England, and many on our own coast, which afford insufficient space for the requisite number of guns in ordinary earthen batteries, and which are so low that such batteries are quite inadmissible."

But another system of protection—Captain Moncrieff's system of gun-carriages—recently tried at Shoeburyness, has made a considerable commotion in foreign military circles, and may be destined, in some form, to prevent the great extension of the old system of fortification, although probably not to supersede the use of the defenses at present constructed. By this system the force of recoil is utilized for the purpose of putting the gun and gunners out of danger, by sinking the gun below the parapet, and that force is stored up by means of a counterweight, to relift the gun to the firing position when reloaded. And by means of mirrors, aim can be taken and the gun discharged without exposing the gunners to any direct aim from the enemy, whether riflemen or others.

Says the "Army and Navy Gazette": The late trials have had for their object less to test the general working of the carriage—which a very few rounds at Woolwich has shown to be satisfactory—as to try whether in respect of facility of working, rapidity, accuracy, and power of sustaining rough usage, the system would furnish satisfactory results. All these points had, one by one, been urged as objections to the system, and one by one have had to be abandoned. The 7-inch $6\frac{1}{2}$-ton gun has shot just as accurately from the Moncrieff carriage as it is capable of doing when mounted in the ordinary way. It has shot well not only at a fixed but at a moving object—thus disposing also of the objection that the carriage would be difficult to manage. On this point further satisfactory evidence is afforded by the fact that three men managed the 22-ton gun, counterweight and carriage, with ease and very fair rapidity. With a full detachment, a rate of fire of one round in 1 min. 32 sec. was attained at a moving object. We have little doubt that it will be found practicable to serve and fire guns mounted on this system at a rate not exceeding a round a minute.

It cannot be doubted, says this authority, that the Moncrieff system is destined to revolutionize the art of defense, except in positions where earthworks are not permissible; positions such as shoals, or spits of land ; or for sea forts like the Plymouth breakwater fort.

We may assume that earthworks will take the place of masonry and iron shields ; and that behind these earthworks will be placed Moncrieff batteries. Or better still, earthworks themselves will disappear and give way in large measure to gun-pits, from which the guns would rise, deliver their fire, and disappear, leaving no mark for the enemy's fire or tangible object of attack. A more embarrassing position for an army advancing through what is deemed an undefended country, and finding itself suddenly face to face with an invisible fortress, cannot well be conceived. But that is the prospect which the adoption of the Moncrieff battery holds out to us ; or we have the prospect of an unbroken line of earth parapet, from behind which at uncertain intervals guns will keep popping up. The defenders in both cases would be absolutely secure against horizontal, and only slightly exposed to vertical fire. Or, if great stress be laid on security against vertical fire, a simple mechanical arrangement can easily be applied which would make gun and gun-pit quite snug. And the important feature of the system is that batteries on this plan can be improvised at a short notice. No expensive or elaborate concrete foundations are required, owing to the absence of a horizontal destructive strain upon the platform or racers (the strain being absorbed by the recoiling carriage); and the creation of a little fortress of gun-pits might be left until war was imminent, so long as we had in store plenty of guns and Moncrieff carriages to place in them.

The unprofessional writers in England, however, go to ridiculous lengths in praising the new system, and decrying forts and all that military science has heretofore accomplished. Says a writer in the "Saturday Review," we have spent £5,000,000 upon works that Captain Moncrieff's discovery had already rendered useless and worse than useless. To which a writer in "Engineering" responds in defence of forts, as follows ; With all the advantages of the Moncrieff "discovery," forts will be just as necessary as ever they were. One of the great objects of defensive works is *an obstruction to the enemy*, which neutralizes his efforts and delays him at points where his power is the least, under the most effective defensive fire; and a means of directing upon him shot, shell, or musketry fire, from a commanding position on every point within range of the defensive weapons. The guns in these constructions may be in casemates or in open batteries. Captain Moncrieff's invention will not enable us to dispense with constructions such as these.

For example, say that a strong force were determined to seize a battery of Moncrieff-mounted guns in a pit—which *is* a species of fortification—they, meeting no hindrance but the shot from the guns, might very quickly, though with decided loss, seize the guns and gunners, while 3 times the same number of men would not be able to seize the same number of guns in a well-fortified position.

Let us suppose a fortress constructed on modern principles—with a glacis, ditch, and covered way. The march of the storming party must be up the inclined plane of the glacis, every inch of which is exposed to the full sweep of the musketry fire from double lines of sharpshooters, on the covered way, covered by an indestructible parapet — the whole breadth of the glacis — and the artillery on the ramparts inside the ditch. It is surely clear to those disposed to think, that an assailant in forcing its way under these conditions up to the ditch, would have suffered far greater loss than in marching up to the edge of a gun-pit. In the latter case his effort would have attained its object; in the former, by far the most dangerous part of the struggle would be only commencing. By escalade, "the most desperate of military undertakings," would be the only chance of ensuring success. While lowering their ladders into the ditch, descending, and raising them against the escarp, the loss of the assailants from the musketry of the *enceinte* and the artillery on the flanks playing upon them with terrible precision, must be fearful. Add to this the reception they would meet with the point of the bayonet when they reached the top of the ladders, with the certainty of many of these, with their human loads, man closely following man, being hurled into the ditch, crushing or demoralizing all below, while the musketry and artillery of the place are continuing to pour upon them their deadliest fire. It is surely unnecessary to follow the scene to greater length, though this is not its end, to prove the immense difference between the defensive power of a well-fortified position and an extended gun-pit.

This authority concludes, that the earlier adoption of the Moncrieff system would not have superseded the necessity for any of the late defensive works in England, but admits that it will greatly add to the defensive power of many of these works. In open batteries the security it will afford to the gun and gunner will be of immense value, and where in these the embrasures would have required iron shields, it is possible £1,000 a gun may be saved by the adoption of the Moncrieff carriage.

Says General Barnard, in the acticle before quoted: Until something is *established* with regard to future construction, we must try to make the best use of such means as we have, and including among them earth obstructions, torpedoes, floating batteries, etc.; and, though last, perhaps not least, the newly devised carriage which I should call the "Moncrieff" were it not that a model by an American "engineer" officer, on precisely the same principle, has been in existence for many years, and that other plans to accomplish the same purpose have been under study, and even trial, with us during the last year or two.

Mr. Bridges Adams, after describing Moncrieff's system, says: So far all appears perfect. The weight of the simple gun is multiplied into a machine tripled or quadrupled without any advantage as a gun of position, but with considerable disadvantage as a weapon of attack, by reason of that very weight, *unless by the use of rails.* The mark is rendered more difficult to aim at, but there is a mark, and a very prominent one, in the form of a mirror, and unless the gun can be made to change its position after every shot, a concentrated fire may be brought to bear upon it as soon as it rises. The guns should therefore be on rails for lateral movement. Any attacking force using the same guns, would have to lay down rails in trenches, with earthwork parapets.

As a means of coast line defense a curvilinear sunk railway, armed with Captain Moncrieff's guns, would be far more formidable than any fixed forts, and far cheaper. But if made fixtures in sunken pits, they must either be covered over, or they would be destroyed by shells, for we may be sure that the process of shelling will assume quite a new phase in accuracy under this new stimulus, and that shells will be planted nearly as accurately as point blank shot, by vertical fire, and even from ships with a stable base in tolerably calm weather.

In conclusion, it should seem that the thorough examination and test of Moncrieff's system is even more important in America than in England. When an invention involving a large expenditure has run the gauntlet of the War Office and Shoeburyness, with perfect success, it can hardly be deemed an "experiment." We think this invention should be taken up at once by our Government, as a tested war machine. There is little doubt that Captain Moncrieff's apparatus would be improved and simplified by the best mechanical engineers, either English or American, and if an inducement were offered to our leading machine builders *now* to study upon it, and prepare for its manufacture, more defensive plant and machinery could be put into the field in three months than the old system could supply in as many years.

DEPHOSPHORIZATION OF IRON FOR BESSEMER STEEL.—Iron from Königshütte with 0.497 per cent. of phosphorus made a very cold short and brittle Bessemer steel. The experiment of refining the iron in a reverberatory furnace by means of jets of air forced down upon its surface with a view to separate phosphorus, led to no favorable result, as the percentage of the same increased. On puddling the iron and reconverting in a cupola into cast-iron, according to Parry's process, the percentage of phosphorus was reduced to 0.1, and the iron could be used for steel. But this reconverted iron was found to be dearer than Cumberland iron delivered at the works in Silesia, and the process was therefore abandoned. Iron when treated this way loses most of its silicon, thereby unfitting it for conversion into Bessemer steel. Chloride of calcium was introduced into the blast furnace with the view to volatilize the phosphorus as chloride of phosphorus, but the experiments led to no result, as the chlorine of the calcium salt was disengaged at far too low a temperature.—WEDDING. *Preuss. Ztschr.*

OXYGEN LIGHT.—The new light—oxygen gas mixed with ordinary street gas—is so far believed in as to be prepared for in the erection of various new buildings. Experiments prove that it is nearly 200 times more brilliant than that emitted by a wax candle, and 14 times more powerful than the illuminative of carburetted hydrogen, and 19½ times that of the gas made by the Manhattan Company, as shown by actual measurement. It is not only more powerful in brilliancy, but, compared with the ordinary gas light, many per cent. cheaper. A thousand cubic feet of oxygen will cost the consumer, it is estimated, $25, and a thousand feet of street gas, $3, or $28 for 2,000 feet of oxygen and carburetted hydrogen, which total of mixed gases is equal in their illuminative quantities to not less than 28,000 feet of the gas that is consumed in our street lamps, at a cost of $74.—*Exchange.*

THERE are 32 manufactories on the line of the Hoosac River, at North and South Adams, employing a capital of from $7,000,000 to $10,000,000, and from 3,000 to 4,000 operatives.

STEAM ON CANALS.—An old method of applying steam to the propulsion of canal boats has been revived on the Erie canal. The driving wheel is placed in the middle of the boat and rolls on the bottom of the canal, being so arranged as to rise and fall with the irregularities of the bottom. The wheel is 1 foot thick and 8 feet in diameter; the periphery is furnished with spikes or spurs, which prevent the wheel from slipping. The speed thus obtained is from 2 to 2½ miles per hour. The extra cost of the boat so furnished was $2,500, but it is believed boats can be built at less expense.

PILING PUDDLE BALLS.—By the so-called Radcliffe process, five or more puddled balls are put together into a large bloom, under a very heavy steam hammer, shingled down into a bloom, passed for a short time into a heating furnace, and rolled off into finished iron not more than half an hour after leaving the puddling furnace. "Engineering" says: "There are many iron-masters who would fear for the quality of the iron knocked down from a pile of puddle balls, with the corresponding internal cavities between them which could hardly fail to be receptacles for masses of cinder."

ICE IN LONDON AND PARIS.—The purest London ice comes from Norway. It is stored there in ice-houses lagged by 2 feet of sawdust, but it wastes 50 per cent. in transportation to the consumer. But the great bulk of the ice is used by the fishmongers and pastry cooks, and is quite impure, coming from ponds and canals. During the present season, Paris has been largely supplied with glacier ice from Switzerland.

NEW YORK MARKET BUILDINGS.—The crusade against these disgraceful and indecent sheds has commenced, and we hope the press, secular and technical, will keep it up till the whole system is reformed. The New York wharves will be next in order.

GOLD AFLOAT.—Since 1859, the United States, Great Britain, and France alone have added 2¼ thousand millions of gold coin to what was afloat before.

RAIL TESTING MACHINE.—Messrs. Wm. Sellers & Co. are building a portable drop for the Philadelphia, Wilmington, and Baltimore Railway, to be used for testing the resistance of rails to wheel blows. A 75-pound weight is raised by hand, falls 4 feet, and is caught on the recoil by an ingenious pawl, so as to strike no short blows. Each blow is recorded by an automatic counter. Some thousands of blows from this drop are considered a nearer approach to actual service than, for instance, the ton weight falling 18 feet, which has been established for steel rails.

ONE IDEA MEN.—An exchange remarks that they are seldom healthy, wealthy, or wise—nature loves variety; to which another answers: *Non omnes omnia possumus.* Concentration of thought and effort in one direction are necessary to distinguished success. Watt was not a jack at all trades—we may add—if he did invent photography as well as the steam engine.

SHIPBUILDING IN THE UNITED STATES, according to the daily press, is reviving. Before the war, 50,000 to 70,000 tons were annually put afloat; the rebellion prostrated the business totally, and since the war, builders have been very timid, and more devoted to securing favorable legislation than improved construction and good contracts.

RIVAL TO THE MISSISSIPPI.—A project is on foot to effect steam communication by water between Ohio and the Gulf of Mexico, at Mobile, passing through the Tennessee River past the muscle shoals, and connecting with the Coosa River by a steam canal thirty miles long.

WALKING MACHINES. — The "steam man" was a most impracticable device for locomotion, but judging from the newspaper accounts, the "walking passenger-car" that appeared lately in New York would seem to be its peer.

DIAMONDS, fastened into a revolving tube, are employed to drill rocks in Reynolds' machine, recently tested in Vermont.

THE BALDWIN LOCOMOTIVE WORKS have received during the past year orders for no less than 224 locomotives. These orders come from all parts of the United States and from South America, and they are being executed at the rate of 15 per month. The capacity of the works will be 20 locomotives per month when the new shops, now well advanced, are completed.

SHINGLE MACHINE.—Walker's is said to be in general favor. The peculiarity which distinguishes it from other machines is in the fact that it does not move the bolt to be sawn to the saw, and then gig it back, or carry it circuitously back to its place, but conveys the saw to and fro to bolts lying on either side of its centre.—*Iron Age.*

STEAM STONE BREAKING HAMMERS, for Lake Superior copper mining, are built by the Michigan Iron Foundry and Machine Shop at Detroit. One of the hammers is said to weigh 50 tons complete. The head falls 9 feet, and strikes a 78-ton blow.

YALE.—The propriety of changing the site of Yale College to more ample grounds is being discussed. The sale of the present location would give a net profit of $200,000 over what it would cost to buy a new and better one.

FORM OF PROJECTILE FOR PENETRATING WATER.—Mr. Whitworth, in a paper before the British Association, gave the results of experiments, which clearly prove that the flat-ended projectile penetrated both water and armor, at an angle, better than the hemispherical or the gothic end.

SPORTING—ITS EFFECT ON NATIONAL CHARACTER.—Lord Wilton attempts to prove, in a book, that only peoples among whom field sports are popular, have achieved or maintained their freedom. The "Pall Mall Gazette" takes his lordship to task as follows: "The sporting classes have furnished out all the divine right, and passive obedience, and high prerogative men. *Our liberties, sad to relate, have been preserved by tailors and cobblers.*"

KRUPP'S STEEL WORKS.—This establishment has been in operation 40 years. It occupies 800 acres of ground, 200 of which are under roof. It employs 8,000 workmen at Essen, and 2,000 more in the mines and furnaces. The following is a list of the plant and tools: 412 melting holes and cementing ovens, 195 steam engines of 2 to 1,000 horse power, 49 steam hammers, of 1 cwt. to 50 tons, 110 smith fires, 318 lathes, 111 planers, 61 end lathes and planers, 84 boring machines, 75 grinding machines, 26 other machine tools, 120 boilers, a gas works supplying 10,000 to 11,000 lights, 6 locomotives, 150 wagons, and 13 miles of railway. In 1866 these works produced 125,000,000 pounds of steel, and had sent out 3,500 steel cannon, worth $7,000,000. The daily consumption of coal is 225 tons. At the Paris Exposition a 15-inch 1,000 pounder steel gun and a steel forging 56 inches in diameter and weighing 80,000 pounds, were exhibited among the products of these works.

THE LARGEST BALLOON.—A gigantic balloon has been constructed at Ashburnham, near Chelsea, and is intended to afford the public some aëronautical experience under circumstances which will insure safety. The balloon is four times the size of that used by Mr. Glaisher, and contains 350,000 cubic feet of gas. It is nearly spherical in shape, and is capable of raising a load of 11 tons. It cost $150,000. It is raised by pure hydrogen, and is drawn down by a chain pulled by a steam engine of 200 horse power. The weight of the cable is $2\frac{1}{2}$ tons, and its length is 2,000 feet. The balloon, car, netting, ropes, and paraphernalia weigh $3\frac{1}{2}$ tons, which, with its cable, make 6 tons of permanent weight, leaving a balance of 5 tons as its available lifting power. Thirty persons are the complement the car is intended to hold, and assuming these to average 150 pounds each, a balance of some 3 tons lifting power is left in favor of the balloon.—*London News.*

STRENGTH OF CORRUGATED IRON.—We have in type valuable papers on this subject by Mr. Hart and Professor Rankine. They will appear in our February number.

MODERN ROLLING-MILL MACHINERY, instead of being the light, rough, foundry-fitted work still seen in some of the older establishments, now rivals marine engineery in solidity and exactness of construction. The results are very clearly seen in increased production, better work, and freedom from breakdowns. The new Abbott rail mill, at Baltimore, built by Matthews & Moore of Philadelphia, started off right at first, and has, without delay, breakdown, or appreciable expense of maintenance, turned out over 50,000 tons of rails the first 2 years. The Pensylvania Steel Company's 24-inch mill at Harrisburg, by the same builders, the heaviest train in this country, has been rolling steel rails for nearly a year, with equally satisfactory results. The Reading Railway Company's mill at Reading, also built by Matthews & Moore, shows an equally good record. This is, everything considered, the most thoroughly built and heavily equipped rail mill we have. Three trains, driven by separate engines, are each 23-inch, with housings suitable for 24-inch rolls, and therefore heavy enough for rolling steel rails, which was in fact contemplated when the mill was erected.

FIVE BESSEMER STEEL WORKS are now running in the United States: the works of John A. Griswold & Co., Troy (small plant, the large plant was burned in October, but is rebuilding); the Pennsylvania Steel Works, Harrisburg; the Freedom Iron and Steel Works, Lewistown, Pa.; the works of E. B. Ward, at Wyandotte, Mich.; the Cleveland Rolling Mill Company's Works, Cleveland.

HAWKINS, HERTHEL & BURRALL, Springfield, Mass., have received an order for the construction of one of their iron bridges over the river at Pawtucket, R. I. The bridge is to be 160 feet in length, with a 20-foot driveway and 2 sidewalks of 6 feet each. The cost, including masonry, will be $14,000.

OCEAN YACHT RACE.—The challenge of the English yacht Cambria has been accepted by the American yacht Dauntless, for a trans-Atlantic race for the Queen's cup won at Cowes by the America 17 years ago.

VAN NOSTRAND'S
ECLECTIC
ENGINEERING MAGAZINE.

NO. II.—FEBRUARY, 1869.—VOL. I.

CHEAP IRON.

The grand requirement of the age is cheap, abundant, and multiform iron; iron at such low prices that constructors can afford to substitute it for weaker and less durable materials, and that all kinds of construction for which iron or its most useful alloy, steel, are alone adapted, will be greatly stimulated. We want iron floors and fronts, iron bridges and sleepers, iron hulls, piers, and forts, and iron framing and facing in general instead of wood. We want steel rails, tyres, wheels, shafting, girders, tension rods, engines, tools and machinery to better resist the wear and strain heretofore inadequately borne by iron. And in addition to these comparatively new and vast applications of iron and steel, we want a greater reproduction of the constructions into which they enter, — *more* steam engines and boilers, more ships and railroads, more iron defences, more agricultural machines, more plant and enginery of every description.

No one thing, not even cheaper coal or cheaper bread, could promote national wealth and progress so directly and rapidly as cheaper iron, for its offices and functions are universal. It shapes, transports, constitutes the physical constructions, and is itself the frame-work of our new civilization. A greater production of iron, even at increased prices, has stimulated commercial and manufacturing enterprises. A vastly greater production at a quarter or half the present cost, would set the world forward a century in a decade.

There is no other subject connected with physical science, of such present absorbing interest, not only to the profession, but to every pursuit associated with or depending upon engineering in its widest sense. The rapid development of new processes, and the promises and expectations of schemers and experimenters in iron and steel, are the *town-talk.* And certainly it is not, as it too often has been, in periods of excitement about new discoveries, all talk. We are entitled to expect immediate results of a character so marked as to visibly better the condition of men and nations. Doubling the life of railroad way and machinery by the use of steel, involves a saving of money that must be universally felt. Reducing the cost of wrought-iron in its almost infinite forms, even to the extent of ten per cent., as seems to be promised by the Ellershausen process, is a blessing as well defined and important as a succession of good harvests.

We devote a considerable space in this number of the Magazine, to articles on various branches of the iron manufacture, and we specially call the attention of blast furnace managers to the subject of *Purifying ores.* Our blast furnace practice most requires improvement, and it would appear to be receiving the least scientific aid, and certainly the smallest amount of experimental inquiry.

Among the more or less developed improvements of the day in the iron and steel manufacture, the Bessemer process, of course, stands at the head. As each new process presents itself, the comprehensiveness of Mr. Bessemer's scheme, and the exhaustiveness of his process, become more apparent. Although soft and ductile steel cannot be produced by it from irons containing phosphorus, nor malleable steel from irons containing a large proportion of sulphur, yet from the greater number of irons in market, it produces not only good steel, but homogeneous steel, cast from the liquid state. No other direct process develops heat enough to liquify the materials treated, and hence all their products are subject to the structural defects of wrought-iron, to welds and consequent lamination under impact, and a treacherous degree of tenacity under strain. The particular feature of Mr. Bessemer's process, showing the remarkable scope and maturity of his design, is the violent mechanical agitation of the iron under treatment, as a means of promoting the intimate mixture of the oxygen and carbon. All other direct processes are defective in this particular, and hence the heat due to the chemical reaction is not rapid and intense enough to promote fluidity. This is true of puddling in all forms, and of Heaton's and Ellershausen's processes. The mere introduction of air to molten cast-iron is not the principal feature of Bessemer's invention, or rather, it is not Bessemer's invention at all; but the blowing of liquid cast-iron into spray, so that the oxygen can get at all parts of it at once—the mechanical air stirring is the essence of Bessemer's invention.

The Ellershausen process, just now attracting such great attention, and hereinafter described, is too new—its product has been subjected to too few analyses, and its *waste* to too few economical tests, to warrant unqualified confidence, although its remarkable success as far as tried, stops the mouth of the most conservative old fogyism.

The Heaton process, already the subject of endless disquisitions, if not quarrels, in the English papers, is also too little tested to warrant positive conclusions. Its advocates base their statements and arguments mostly on assumptions, and the opposition on *one* set of analyses by the oft-quoted and much pulled about Dr. Miller.

We have referred in another place to the Siemens-Martin process, a proved and established success, and to the Siemens furnace, an accessory to cheap iron and steel, of hardly less value than either of the processes mentioned.

The *refining* of iron is certainly making good progress; we wish we could speak as confidently of the manufacture of pig. This is the weak point in the great scheme of cheap iron. Bessemer may blow, and Siemens may heat never so wisely, but if our smelters do not cultivate more intimate relations with chemical and metallurgical science, the iron millennium will not dawn upon this generation.

UNDERGROUND CITY RAILWAYS.

ENGINEERING DIFFICULTIES — PRACTICAL AND COMMERCIAL SUCCESS—THE LONDON METROPOLITAN RAILWAY.

Under the title of "The Great Railway in Diluvia," "Engineering" gives a graphic account of the difficulties encountered in constructing the Metropolitan Railway, the remarkable energy and success with which they have been overcome, and the extent of the excavations, as compared with other artificial subterranean works, from which we extract the following :—

Beyond the minor troubles to which all railway engineers are born—those with committees, boards, vestries, juries, and the owners and agents of every piece of property at which they dare so much as to look—the underground railway has presented difficulties, at almost every yard, sufficient to make or unmake a professional reputation, according to the success or failure of the attempt to overcome them. The ground had to be studied everywhere, almost, indeed, inch by inch, filled as it was, at so many points, with the gnarled and interlacing ramifications of half-a-dozen gas and water works, and the less easily diverted channels of the metropolitan sewers. In one place a row of houses was ready to move bodily forward into the tunnel; in another a great sewer, although approached but at a respectful distance, was ready to burst and flood a whole neighborhood. This, indeed, actually did happen in the Fleet valley. In Park-crescent a fine house, one in a large sweep of mansions, had to be carefully measured, its every detail drawn, then taken down, and when the railway had been completed just beneath it, rebuilt as before, and so exactly that you could not possibly distinguish it from its neighbors.

The work in carrying the extension line beneath a noble row of houses in Pembridge-square, transferring the bearing of the walls of these houses to a new foundation, was of the highest interest, and displayed great boldness.

The diversion of the large sewers was in many cases a delicate operation. In some instances a 9 feet sewer is carried over, and in others under, the rails. The Ranleigh sewer is carried over a station in a cast-iron tube 9 feet in diameter, between wrought-iron girders having a clear span of 67 feet. Near the Victoria station, the level of the rails is 21 feet 9 inches below high-water mark in the Thames, and a sewer is carried over the railway in a cast-iron tube 14 feet wide and 11½ feet high. The distance from the invert of this sewer to the rails is only 13 feet 7 inches, and it was necessary to arrange the connecting flanges of the plates and the cross girders on the skew, to obtain a sufficient clearance. The tube is protected by a brick arch turned over it, which carries the street traffic. The drainage of the railway is done by pumping-engines.

One of the neatest flights of the invention of which necessity is the mother, was the taking of the extension line beneath the West London Railway, where the difference between the crown of the lower arch and the level of the upper rails was but a few inches, and this without the least interruption of a traffic of 400 trains a day. The operation amounted to taking out the "bottom" of a railway without delaying a single one of the trains almost constantly passing over it. The rails of the West London line were supported upon longitudinal sleepers, carried upon transverse timbers, projecting 7 feet on each side of the trenches that were excavated for the side walls of the low level line; between the transverse timbers the permanent girders were placed, and the side walls built up in detail to their undersides. The length of this crossing is 119 yards. In getting in the foundation of this work, considerable trouble arose from the great depth of the clay below the surface, and it was found necessary to enclose an area of about 920 feet in length, and the width of the railway at formation, with a clay puddled dam 5 feet thick, and varying from 6 to 20 feet in depth.

A little to the west of the Aldersgate-street station stands the now practically completed meat market at Smithfield, the entire area of which at the rail level is converted into a depot, through which runs the Metropolitan Widening, devoted to the service of the trains of the Great Northern, Great Western, and Midland Railways, whilst the London, Chatham, and Dover line makes a junction with it at the entrance to the depot. The size of the market within the retaining walls, which are deeply vaulted, is 625 feet by 240 feet, the vaults serving as valuable storage-room, and the whole of the depot is roofed over with a series of brick arches, turned between a system of girders, resting upon wrought-iron columns. The upper surface of this covering forms the floor of the market on the street level, between which and the platforms of the depot beneath, communication is maintained by fifteen hoists worked by hydraulic machinery, now being completed.

In structure merely, the works upon the Metropolitan Widening, the Smithfield market works in connection with the railway, the bell-mouthed junctions, the portions in which the arch of the tunnel is of iron, and others where the haunches are of iron, together with the extensive employment of iron centering, give special interest to the underground railway, even when examined by the most practical engineer.

The part of the Metropolitan Railway now open has carried its 120,000 passengers in a single day, a traffic hardly within the powers of the 6,000 cabs of London and the 600 *omnibi* of the General Omnibus Company; a traffic not often matched by that over London Bridge, and hardly ever equalled by that carried by the other 10 metropolitan railways taken collectively. There are often, at the same moment of time, 10 well-filled trains on the double line between Bishop's-road and Moorgate-street, containing 3,000 men, women, and children; yet all this vast movement underground is unseen, unheard, and in hardly more than 20 minutes, these thousands reappear in the streets, three, four, or more miles from where they dived into the earth.

A very important consideration—which the citizens of New York will do well to ponder—is that the portion of the London line already open, now *pays*—pays £1,000 per mile per week of gross traffic, and 7 per cent. dividend upon a heavy capital account.

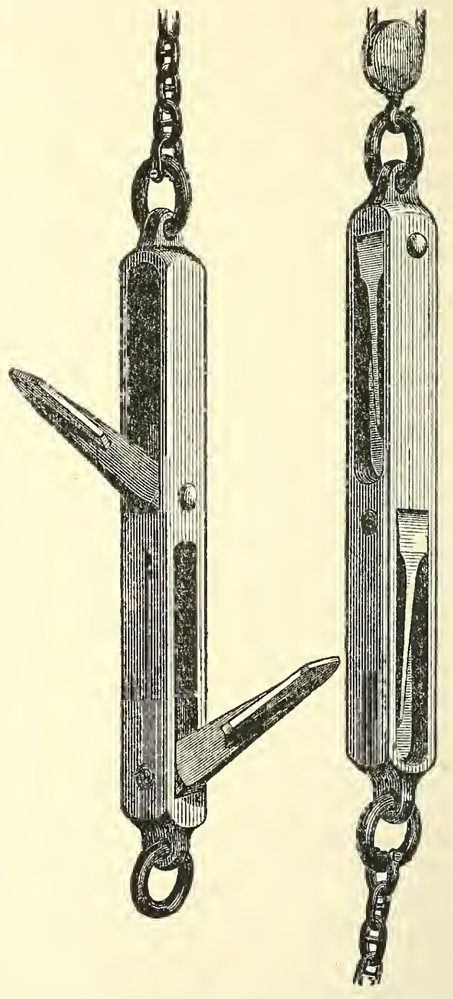
Where the line is fully completed, it will be nearly 8 miles long—a series of tunnels, as long, collectively, as the Mount Cenis tunnel, if not indeed longer, and this besides some few miles of "opens," partly in sloped cuttings, but for the greater distance between strongly buttressed and counterforted retaining walls. Although this tunnel will constitute over 20 acres of cavern—it is small compared with the deserted quarries beneath Paris, quarries now known to have an extent of more than 200 acres, and of which but a comparatively small portion is occupied by the Catacombs. Of building stone alone, upwards of 14,000,000 cubic yards are estimated to have been taken from them. None of our mines of coal or ironstone, have been yet disembowelled to anything like this extent.

"Engineering" adds,—and we beg the people of New York to attend: In New York, the third city in rank in Christendom, and where everybody is in a hurry, and where steam is turned to almost every possible purpose, there is no underground railway, nor is there soon likely to be, although the "down-town" merchants are compelled to ride four, five, or six miles each way, daily, between their homes and places of business.

The Darwinian Theory of the origin of the species is:—First, that variations so slight as not to form distinctive features of classification, are constantly occurring in the reproduction of plants and animals; second, that these variations of form are capable of transmission to progeny, the resulting characteristic generally being intensified in transmission; third, that whenever the variations give their inheritors peculiar advantages in obtaining sustenance, etc., over that possessed by their fellows, they will live longer, will procreate more, and consequently, in the lapse of ages, will extinguish the weaker types. Experiments on plants and animals conducted on this theory, have even in a short time produced astonishing differences in form, color, and habits. This theory, called "natural selection," is gaining ground among naturalists and philosophers.

WITTRAM'S ANCHOR.

The ingenuity of inventors has long been taxed, in the endeavor to produce an anchor which should come nearer than do any of the old style, to the ideal of a perfect ground tackle. The first successful attempt to improve upon the old cumbrous anchor, with its massive shank and flukes, and its huge wooden stock, was made when iron movable stocks were introduced.



The next improvement of importance was the patent known as Porter's, afterwards improved by Trotman, in which the flukes moved on a bolt in the crown. This anchor has been generally adopted in the British Navy, and also in the merchant services of various nations. Recently, Mr. Frederick Wittram, of San Francisco (now in New York city), has invented an anchor which is radically different from all others. When this anchor is not in use, the flukes lie concealed within the body of the shank like the blade of a pocket-knife, and therefore it can be as compactly stowed as a block of wood of the size of the shank, as shown by Fig. 2 in the engraving. On throwing the anchor overboard, the flukes swing out, as in Fig. 1, and no matter how the anchor falls, one or both flukes are sure to take hold, thus rendering it impossible for the anchor to drag. As there are no projections, such as the stock, or an unused arm, it therefore cannot foul as other anchors frequently do. In weight it is one-third less than ordinary anchors of equal capacity. The repeated tests which have been made of its practical utility have been all highly satisfactory, and it is now attracting much attention from scientific and experienced nautical men.

RIVETS.—Mr. Clark, the English bridge engineer, who has made experiments to determine the shearing strength of rivet iron, mentions the fact that rivets, worked hot, contract in cooling, and draw the plates together, thereby causing friction. From this he infers that the value of the rivet is greater than the shearing strength of the rivet iron by the amount of the friction. Later experiments on riveted work show, however, that the value of rivets falls below that given by Mr. Clark for rivet iron, although it includes friction also. Mr. Fairbairn, in his "Useful Information for Engineers," mentions this fact about the friction not appearing to help the rivets, but does not attempt to account for it. Mr. Reed, in his recent work on shipbuilding, explains it by saying that the friction does help the rivet, but that the rivet is much weakened by the working and by contraction during cooling. To show the extent of this, he takes Mr. Clark's values for the shearing strength of rivet iron; experiments at Chatham Dockyard supply the shearing strength of rivets in place (including friction), and some experiments made at Pembroke (which are described in the book) give the amount of the friction; and by deducting the difference between the two last from the first, he gets the amount which the rivet has been weakened. To take an example of a three-quarter rivet:—Shearing strength of the rivet iron=19·52 tons for a double shear; double shearing force of a three-quarter rivet in place=18 tons; mean value of the friction caused by a three-quarter rivet=4.6 tons, from which we find that the shearing strength of the rivet amounts to 13½ tons, or about 6 tons less than the double shearing strength of the iron from which it was made. Mr. Reed conjectures in the text that the principal cause of this loss of strength in the finished rivet is the interior stress of the iron due to the contraction, and he adds that there is probably a further reduction due to the manipulation which the rivet has to undergo in being manufactured and put in place.—*Mechanics' Magazine.*

SUPERSATURATED SOLUTIONS.—Mr. Charles Tomlinson, F. R. S., has been experimenting and theorizing upon the subject of the phenomena of supersaturation in saline solutions, and has communicated to the Royal Society his conclusions and the grounds upon which they are based. The conclusions arrived at by Mr. Tomlinson are: (1) That a number of hydrated salts form supersaturated solutions, and remain so even at low temperatures simply from the absence of a nucleus to start the crystallization; (2) That a nucleus is a body that has a stronger adhesion for the salt than for the water which holds the salt in solution, a state of things brought about by the absence of chemical purity; (3) That three or four salts form supersaturated solutions, which in cooling down deposit a modified salt or one of a lower degree of hydration than the normal salts; (4) That this modified salt is formed first by the deposit, in small quantity, of the anhydrous salt, which entering into solution, forms a dense lower stratum containing less water than the rest of the solution, in which lower stratum the modified salt is formed; (5) That salts of a lower degree of hydration form supersaturated solutions, which on reduction of temperature, or by the action of a nucleus, deposit the excess of salt that held the solutions supersaturated, leaving them merely saturated.

WELDING OF COPPER.

Translated from Dingler's Polytechnic Journal, by John B. Pearse.

Mr. Philip Rust, Bavarian Inspector of Salt Works, writes as follows: The great obstacle heretofore experienced in welding copper, has been that the oxide formed is not fusible. Now, if any fusible compound of this oxide could be found, it would render such a weld possible. We find in mineralogy two copper salts of phosphoric acid, viz.: Libethenite and pseudo-malachite, each of which melts readily before the blowpipe. It was therefore natural to suppose that a salt which contained free phosphoric acid, or which would yield the same at a red heat, would make the weld easy by removing the oxide as a fusible slag.

The first trial was made with microcosonic salt (phosphate of soda and ammonia), and succeeded perfectly. As this salt was quite dear, it was found advisable to use a mixture of 1 part phosphate of soda and 2 parts boracic acid, which answered the same purpose as the original compound, with the exception that the slag formed was not quite as fusible as before.

This welding powder should be strewn on the surface of the copper at a red heat; the pieces should then be heated up to a full cherry red or yellow heat, and brought immediately under the hammer, when they may be as readily welded as iron itself. For instance, it is possible to weld together a small rod of copper which has been broken; the ends should be beveled, laid on one another, seized by a pair of tongs, and placed together with the latter in the fire and heated; the welding powder should then be strewn on the ends, which, after a further heating, may be welded so soundly as to bend and stretch as if they had never been broken.

M. Rust had in as long ago as 1854, welded strips of copper plate together and drawn them into a rod; he had also made a chain, the links of which had been made of pretty thick wire and welded.

It is necessary to carefully observe two things in the course of the operation. 1st. The greatest care must be taken that no charcoal or other solid carbon comes into contact with the points to be welded, as otherwise phosphide of copper would be formed, which would cover the surface of the copper and effectually prevent a weld. In this case it is only by careful treatment in an oxidizing fire and plentiful application of the welding powder that the copper can again be welded. It is therefore advisable to heat the copper in flame, as for instance a gas flame.

2nd. As copper is a much softer metal than iron, it is much softer at the required heat, than the latter at its welding heat,—and the parts welded cannot offer any great resistance to the blows of the hammer. They must therefore be so shaped as to be enabled to resist such blows as well as may be, and it is also well to use a wooden hammer, which does not exercise so great a force on account of its lightness.

Hydraulic Dredging.—If sand is drawn along with water into a centrifugal pump, it will be driven forward and thrown out with the water. Messrs. Gwynne, of London, therefore propose, in order to dredge at a depth of over 60 feet for the Bermuda floating dock, to stir up the sand of the sea bottom mechanically, to place their centrifugal pump close to the bottom, and thus to excavate it—pump it out. A large wrought-iron tube, attached to the dredging barge and swinging like the bucket-frame of a dredging machine, carries a pump at the bottom. The shaft that drives the pump passes down the centre of the tube, and carries also a series of screw-blades which stir up the sand. A hood, at the end of the tube, prevents the escape of the sand, so that it is drawn into the pump while momentarily suspended in the water. The work to be done is, simply overcoming the difference of weight between sand and water, raising both a short distance above the water-line, and overcoming the friction of the mass rising in the tube.

Ichabod Washburn, who died in Worcester, Massachusetts, on December 30, has been identified with the manufacture of machinery in this country for nearly half a century. He was as generous as he was successful. Among his gifts were a fund of $200,000, a machine shop fully equipped, and $50,000 working capital, to the Worcester County Institute of Industrial Science.

COMPARISON BETWEEN THE UNIFORMITY OF BESSEMER STEEL AND IRON RAILS.

EXPERIMENTS MADE FOR THE CENTRAL RAILWAY OF ORLEANS AT THE TERRE NOIRE WORKS, AND THOSE OF PETER ASHCROFT, ESQ., ON ENGLISH IRON RAILS.

BY JOHN B. PEARSE.

Conditions.—1. Two ingots shall be taken at hazard out of the same charge and submitted to the subjoined tests in order to ascertain whether their qualities are identical. These trials shall be repeated upon three different charges.

2. Choose any charge as a typical one, and of this take one ingot and submit it to the following tests. Make 6 charges with the object of making them identical with the typical one, and of each of these 6 charges take an ingot and submit it to the same tests, and endeavor to obtain results similar to those obtained from the typical charges.

The desired tests are as follows:

1. The ingots chosen for each series of tests shall be rolled into rails in the ordinary way.

2. Each rail shall be submitted to a deflection test on the following conditions: The rail placed on supports 1 metre apart is to be submitted to pressure in a hydraulic press. Ascertain the deflection under pressure, and the permanent deflection after removal of the pressure.

The hydraulic press used was constructed at Graffenstaden and is fed by 3 pumps worked by eccentrics, whose stroke is so regulated that the supply of water shall be as uniform as possible.

3. Pieces of these rails, of a length of 2 metres, shall be tested by a falling weight under the following conditions:

The rail is placed on 2 supports, the centres of which are distant 1.1 metres from each other; these supports rest directly on a block of iron weighing 10,000 kilogrammes ($9\frac{1886}{2240}$ tons). The weight of the drop shall be 300 kilogrammes (661.36 lbs.).

The subjoined table exhibits the results obtained in the above series of tests:

2,000	26	23	25	26	25	26	25
2,250	37	31	33	37	35	37	36

The following conclusions flow naturally from the above tests :

1. The first series demonstrates the practical identity of 2 ingots chosen at random from the same charge. The regularity of the results is remarkable up to the pressure of 25,000 kilogrammes (about 25 tons), which represents quite nearly the *limit of elasticity.*

Above this limit the differences are still inconsiderable compared to weights (or pressure amounting to weight) borne.

2. The first series develops a remarkable regularity in the charges, although not made with the object of proving any identity.

Charge 581 is a little harder than the others, but the results up to the limit of elasticity do not vary much from those given by the other ingots, and the variation is too inconsiderable to have any practical influence.

3. The second series shows the practical identity of the 6 ingots with the 7 or *type* ingot. The latter is a little softer than the ingots of the 3 charges in the first series. It was made so designedly, and its qualities were reproduced quite closely, as the differences in the permanent deflection or set are within a few tenths of a millimetre. As in the previous series, the differences become great only when the limit of elasticity is passed.

4. The drop tests show uniform results, which are in harmony with those given under pressure. The variations bring out the slight differences in the hardness of the various ingots. For example, the metal of charge 581 is a little stiffer than that of charges 577 and 580. It is also apparent that the ingots of the second series were softer than those of the first.

The experiments were conducted with every care, by the engineers of the Terre Noire Works in presence of M. Delom, engineer of the Orleans road, on the part of the railway company.

These results are very interesting as showing a practical identity in the products of the Bessemer process. It would be difficult to find any such series of iron

rails made with puddled steel or hard iron heads. The following series of tests made by Mr. Peter Ashcroft, engineer to the South Eastern Railway Company, shows how much iron rails made by the same companies may vary in strength. The tests are classified according to the company upon whose rails they were made. The remarks are those of Mr. Ashcroft.

These trials were published in "Engineering" and have been rearranged for the purpose of showing distinctly how much the rails of each maker varied. The tests show that the majority of the rails tried excepting those of one company (Ebbw Vale) were extremely brittle and unsafe. It is very probable that the slabs which are made from old rails and used in the formation of the rail piles vary greatly in quality and may indeed be altogether different; that is, one slab might easily be cold short, while its neighbor was red short. It would not be improbable to suppose that in some parts of the country a rail pile might easily be composed of slabs from rails of 3 or 4 different makers, with tops and bottoms puddled and rolled at the mill. Now such a rail would be composed of layers of different material varying in strength, and it is quite natural to conclude that some of the layers would be so weak as to partially destroy the strength of the rail itself, by giving way before the stronger parts had been materially strained. That is, a strong flange is of no use with a web which would give way on strain, or a head which was made so hard as to crumble on the reception of a blow, or under the constant succession of blows to which it is exposed in the track. It is also probable that a pile may be so heated as to be burnt in some parts while quite sound in others, while the temperature at which it is necessary to weld the slabs together is so near that at which they may be burnt, that many tons of piles have been burnt in the furnace by the mere change of the light in which the furnace was placed. When the poor quality of iron used for rails is taken into consideration along with the manner in which the same is worked up, it is quite obvious that a great deal of irregularity is natural to the whole series of operations.

THE ELLERSHAUSEN PROCESS.

The recent and remarkable invention of Mr. Ellershausen, which is now regularly in use in Pittsburg, and is being rapidly introduced all over the country, has greatly advanced the solution of this important problem. So many new steel and iron processes are brought to notice every day, that the unprofessional reader cannot keep track of their names and aims. The value of this process may be inferred from the fact that a no less respectable Board of Trustees than Messrs. Asam L. Hewitt, E. B. Ward, Jas. Harrison, Jr., and several Pittsburg iron masters, are now granting licenses under the Ellershausen patents.

The process consists in the conversion of crude cast iron, as it runs from the smelting furnace, into wrought iron, by the simple admixture of granulated iron ore. It is carried out at the works of Messrs. Shonberger, at Pittsburg, in the following manner: On the casting-floor of the smelting furnace a cast-iron turntable, about 18 ft. in diameter, is revolved on rollers by a small steam-engine. Upon the outside edge of the table stand a row of cast-iron partitions, forming boxes, say 20 inches wide and 10 inches high, open at the top. Just above the circle of boxes stands a stationary, wide-mouthed spout, terminating in the tap-hole of the furnace. When the furnace is tapped, the liquid iron runs down this spout and falls out of it in a thin stream into the boxes as they slowly revolve under it, depositing in each a film of iron, say one-eighth of an inch thick. But, before the fall of melted iron reaches the boxes, it is intercepted, or rather crossed, at right angles, by a thin fall of pulverized iron ore, which also runs out of a wide spout from a reservoir above. These two streams or falls are of about equal volume, say one-quarter of an inch deep and 20 inches wide. A workman, with a bar in the tap-hole, regulates the stream of iron, and the iron spout from which the liquid metal falls into the boxes is removable; other spouts, previously coated with loam and dried, being attached to a common revolving frame, so as to be ready for use when the loam covering of the first becomes cracked or removed.

The thin layers of iron and ore soon chill and solidify, so that by taking away the outer partition of the boxes (which form the rim of the turn-table), they may be removed in cakes of the size of the boxes, and weighing about 200 lbs. each. Four of these cakes or blooms are put into a reverberatory puddling or heating furnace, and raised to a bright yellow heat. They will not melt at this heat, but become softened so as to be easily broken up with a bar. The four blooms are formed, in the furnace, by the "rabble" of the workman, as in ordinary puddling operations, into eight balls. The balls are brought out, one after another, squeezed in the ordinary "squeezers" to expel the cinder and superfluous ore, and then rolled into wrought-iron bars, which are now ready for market, or for further reduction into smaller finished forms.

The chemistry of the operation is as follows: The crude cast-iron contains say 5 per cent. of carbon and 2 per cent. of silicon, and more or less sulphur, phosphorus, and other impurities. In the Bessemer process, the oxygen of the air, blown into the liquid iron, combines with this carbon and these other impurities, and not only removes them, but leaves the pure iron in a liquid state, from which it can be cast into homogeneous masses of any size. In the puddling process, the oxygen of the air and of the ore, or other "fettling" put into the furnace with the iron, combines with and eliminates the impurities, which are afterward squeezed out of the pasty mass by the squeezers and rolls. This process is long and comparatively expensive, because the mixture of oxygen or oxygen-bearing substances is not made intimate with the iron except by long stirring, which is not only skilful, but exhausting work.

In the Ellershausen process, the oxygen of the ore or oxide of iron (magnetic oxide is preferred) combines with the carbon and impurities, eliminating them as in the puddling process, and the iron of the ore increases the product. The chemical combination of the ore and the liquid crude iron appears to take place partly at the time of their contact when falling and lying upon the turn-table, and partly where the reheating occurs in the furnace. It seems impossible that a reaction which is so violent in the Bessemer process, and so prolonged in puddling, should take place so quickly and quietly in the new process; but the fact that the cakes of iron and ore do not melt by subsequent heating, as cast-iron would, proves that its nature is changed by the first contact of the ore. The removal of sulphur and of phosphorus also seems more thorough than in the other processes. Analyses at different stages of the operation will throw more light on this question.

The remarkable feature of the Ellershausen process is that absolutely no skill is required to carry it out. The proportion of ore mixed is intended to be about 30 per cent; but if too much is added, it is readily squeezed out with the slag, and seems to do no harm. The subsequent heating occupies about half an hour. "Puddle bar," the product obtained from the first rolling of the product of the puddling furnace, is never marketable or finished iron. It is usually very ragged and unsound, and requires subsequent piling, reheating, and rerolling, to expel the impurities and to give it soundness and solidity. The new process appears to produce merchantable iron at the first rolling, and, at Pittsburg, from a very inferior pig-iron, made of one-half sulphurous Canada ores, and one-quarter Lake Superior and one-quarter Iron Mountain ores.

The thoroughness and rapidity of the purification by this process evidently depend on the intimacy of the mixture of iron and ore. This intimate mixture is also the essence of the Bessemer process. In fact, to Mr. Bessemer's original apprehension of this idea of intimate mechanical mixture, the greatest modern improvements in the iron manufacture are due.

The Ellershausen process is said to decrease the cost of wrought-iron from $10 to $20 or $30 per ton, according to the materials used and the form of product required. That it is a success is amply proved by regular working at Pittsburg and many experiments elsewhere; and if anything like this economy can be realized, its value to the public will only be exceeded by that of the Bessemer process. The latter process, however, produces *steel*, which is absolutely homogeneous and of regulated hardness, according to the wear and service required, and hence indispensable for rails, tires, and various machinery purposes. Any iron product that is not *cast* from a liquid state, is subject to all the structural defects of ordinary wrought-iron.—*New York Times.*

ENGINEERS IN PARLIAMENT.—"Never," says "Engineering," "have the most important industrial interests of the kingdom been so fully represented as in the new Parliament." It includes, engineers, contractors, ironmasters, manufacturers and the owners of collieries. Among them are, Mr. George Elliott, Prest. of the North of England Inst. of Mining Engineers, an ironmaster who finds employment for 10,000 men; Mr. John Lancaster, Chairman of the Mining Association of Great Britain, head of the Wigan Iron and Coal Company, and less favorably known in America in connection with Captain Semmes of the Alabama; Mr. Richard Fothergill of the Taff Vale Ironworks; Mr. A. C. Sheriff, chairman of the Metropolitan District Railway; Mr. Joseph D'Aquilar Sumuda, Shipbuilder; Sir Daniel Gooch, late Locomotive Superintendent of the Great Western Railway; Mr. John Robinson McClean, late President of the Institution of Civil Engineers; Mr. John Platt, Manufacturing Engineer; Mr. John Hick, Engine-builder; Mr. John Laird, Shipbuilder; Dr. Lyon Playfair of the University of Edinburgh; also, Messrs. John Miller, Charles E. Cawley, Sir Richard Atwood Glass, Messrs. Thomas Brassey, James Howard, and Charles Seely, Engineers, and Messrs. Bolckow, Brogden, Beaumont, Winn, Plimsoll, Rylands and Samuelson, Ironmasters.

THE UPPER HUDSON—SLACKWATER NAVIGATION.—The report of the State Engineer for 1867 embodies the report of the surveys made in 1866 by Samuel McElroy, C.E., for the improvement of the Hudson river for slackwater navigation from Troy to Fort Edward, about 40 miles, and a corresponding improvement of the Champlain Canal from Fort Edward to Lake Champlain, about 25 miles, with locks 225 feet by 30½ feet, adapted to 8 feet water-way; and also the comparative cost of improving the Champlain Canal from Troy to Whitehall, with locks 225 feet by 25, and 7 feet water-way. It appears that a dam at the Highlands, 150 feet high, would turn the stream into Lake Champlain and the St. Lawrence; that the remedy which New York harbor needs for the difficulties of navigation at

Hell Gate from the swift tidal currents, and at other points for ice fields and deposits of silt, and at Sandy Hook, would be found by connecting New York and Brooklyn with a masonry dyke say 400 feet wide, with 2 or more ship locks, and by making a ship canal of the Harlem River, so that the whole volume of the North River could go out to sea, and the present tidal flux and reflux be prevented on the East River, and the facilities of Sound and river commerce be turned into their natural channel at the head of New York Island. This would also solve effectually the problem of connecting New York and Brooklyn.

It is also proposed to examine the gorges of the Hudson river above Fort Edward, to determine the feasibility of a plan for retaining the freshet supplies, so as so prevent the periodical floods which have always proved so destructive above Albany.

The details of the report show that on a comparison of the items of cost, the sum of $4,534,379 will secure 8 feet water-way by the river plan, from Troy to Whitehall, while it will cost $5,866,851 to secure 7 feet water-way by the canal plan, and that the "commercial, military, and mechanical advantages are distinctly in favor of the river plan;" the value of the developed mill power alone being shown to be about $4,334,600.

NEW SYSTEM OF BOILING SUGAR.

In an ordinary vacuum pan, the top of the liquid alone forms the evaporating surface, and evaporation would, of course, be more rapid were a greater portion of the liquid exposed. An improvement by Mr. Tooth consists in pumping the juice down from the top of the vacuum pan, at the moment of granulation, through a rose. The juice is thus distributed in small streams through the air contained in the evaporating vacuum chamber, and the surface exposed, as compared with the old system, is said to be as 1,000 to 50. The evaporating chamber differs from the old vacuum pans in shape, being, to speak roughly, a long cylinder, with the ordinary round pan at the top and bottom. The juice, before reaching the evaporating chamber, is pumped up through a number of pipes surrounded by steam in a cylinder. The following advantages are stated by the inventor to be secured by this process: 1. The juice is protected from excessive and long-continued heat. 2. Long exposure to the injurious influence of the atmosphere is avoided. 3. Great rapidity in carrying on the evaporation is secured. 4. The juice is transferred to the vacuum pan (or evaporating chamber) immediately after defecation and filtration, avoiding the necessity of open pans. 5. Any extent of heating and evaporating surface is easily obtained. 6. The cost of fuel is greatly lessened. 7. Vacuum pans now in use may be made available for the improved system at a comparatively small cost. 8. The finest sugar is produced without the expense of animal charcoal, and the crystallization being perfect, there is no loss by drainage. 9. There is no formation of molasses beyond that naturally existing in the juice, as the temperature never need exceed 140° to 160° Fahr. 10. The system is also useful in beetroot sugar manufactories. There is an arrangement by which the clogging of the rose, through which the partly-granulated sugar passes, is remedied. The idea of exposing a greater surface to evaporation seems to us excellent in theory, but it belongs, of course, to practical men to say if it will work. Mr. Tooth has another patent to compete with Mr. Fryer's boncretor, for rapid and cheap evaporation. This consists in passing the partially granulated juice through a rose, and letting it drop down through a long cylinder or tower filled with heated air. The patentee states that the juice reaches the bottom in the shape of sugar.—*Produce Market Review.*

Another Great Eastern.—Mr. Thomas Silver has designed a ship of Great Eastern proportions except as to depth; the draft is to be 18 instead of 28 feet. The vessel is intended to carry 4 times as many passengers as the present Cunarders, and to have Christian beds and rooms for their accommodation.

High-lift Centrifugal Pump. — Messrs. Gwynne & Co., London, are constructing a centrifugal pump, to draw from a depth of 18 feet and force over a stand-pipe 114 feet high—the greatest lift yet attempted with this kind of machine. The pump has a disc 2 feet in diameter, and is to run at 910 revolutions per minute.

RECENT CIVIL ENGINEERING WORKS.

BRIDGES, HARBORS, AND DOCKS.

Compiled from "Engineering," and other authorities.

English Bridges.—In England two fine bridges were completed and opened in 1868. The great bridge of the London and North-Western Railway over the Mersey at Runcorn, besides its long approaches, has three spans of lattice girders of 300 feet clear opening each. The construction of this bridge presents no new feature of interest.

The Solway viaduct, carried out upon the plans of Mr. James Brunlees, is about a mile in length. It has 161 spans of 30 feet each of light wrought-iron girders, besides a swing bridge giving two 50 feet openings. The bridge is supported upon cast-iron piles, driven through the shifting sand into the gravel below. About 1,900 tons of wrought, and 2,300 tons of cast iron have been worked into this structure.

The new bridge at Blackfriars (pronounced by the President of the Institute of British Architects, the "ugliest bridge of its size in Europe") has a central arch of 185 feet, besides 2 arches of 175 feet, and 2 of 155 feet. The arches are of wrought iron; the foundations have been built up in caissons; the width between parapets is 75 feet. The bridge is nearly completed.

No masonry bridges are in progress, and it is the opinion of some of our best engineers that the age of stone has ended, and that iron has permanently taken its place. No one of our English bridge engineers has yet adopted steel; but this is best explained by the fact that while steel is so much more costly than iron, its great advantage—that of saving weight—is shown chiefly in the case of large spans, and no long span bridges are now in course of construction in England.

American Bridges.—For large bridge works in progress we are to look abroad. In America the widest span of suspension bridge yet achieved—viz, 1,268 feet—has been carried over the Niagara river, almost immediately below the great cataract, and nearly two miles above the railway suspension bridge. The length of suspended platform is 1,240 feet; height above the water, 190 feet; length of part resting directly on cables, 635 feet; height of towers, 100 and 105 feet; base of towers, 28 feet square; width of roadway, 10 feet. The 2 cables are 7 inches diameter each. The weight of the suspended load is 250 tons. The work was designed and carried out by a Canadian engineer, Mr. Samuel Keefer.

Two other great suspension bridges are proposed in America, and it is confidently anticipated that both will be begun and completed. The East River Bridge at New York, projected by Mr. John A. Roebling, is to have a single suspension span of 1,600 feet, and to be in all one mile in length. The height of the roadway is 130 feet; width, 80 feet; height of towers, 263 feet. The Cornwall (railway) bridge is to be carried over the river Hudson, at some distance above New York, in a single span of 1,800 feet; height above water, 155 feet; height of towers above water, 280 feet; total suspended weight, 9,651 tons. The last-named work has been designed by Mr. Julius W. Adams, who has a high reputation in America as a sound and successful engineer, his name alone being sufficient to protect the undertaking in question from any suspicion of its being a mere idle scheme.

Of the iron bridges in progress in America, one over the river Ohio at Louisville, will be one mile in length, and, besides a number of smaller spans, will have 2 of 370 feet each, 6 of 245 feet 6 inches, two of 227 feet, three of 210 feet, &c.* A timber bridge for railway purposes, lately completed over the river Mississippi, at Quincy, has a pivot span upwards of 360 feet long, covering two openings of 180 feet each.

One of the most important works yet commenced in the United States, is the great railway and roadway bridge over the river Mississippi at St. Louis. This work has been fully described and discussed in the last volume of "Engineering." As designed by Capt. Eads, it is to have three arches of steel, the middle arch being of the enormous length of 515 feet.

The iron bridge just completed over the Mississippi at Dubuqe, was built from the designs of J. H. Linville, Esq., President of the Keystone Bridge Co. It consists of 7 spans, 2 of 250 feet, 4 of 225 feet, and 1 of 360 feet resting on the pivot pier, leaving the opening 160 feet

* For particulars see "Engineering," Vol. V., page 506.

wide on each side of the pier. The total length of the bridge is 1,760 feet, or exactly one-third of a mile. The truss is 28 feet high and 16 feet wide in the clear. The lower chord is $31\frac{1}{2}$ feet above low water. The eastern approach is through a tunnel 835 feet long.

Continental Bridges.—On the Continent the finest bridge completed and opened during the year, is Mr. R. M. Ordish's elegant work, the Franz Joseph rigid suspension bridge over the Moldau, at Prague. This is the first practical embodiment of a principle for which Mr. Ordish has contended for so many years, that of straight inclined suspension rods, with a light curved chain to support their own weight in so far as to prevent sagging. This bridge, with a span of 492 feet between centres of towers, a vertical depth between centres of suspension rods of 61 feet 3 inches, and a total length of 820 feet, has been heavily tested with a very moderate deflection, while it possesses also great steadiness under passing loads.

Among the Continental works nearly finished, and soon to be opened, is the magnificent railway bridge in Holland, at Kuilenburg, over the Lek, one of the channels by which the river Rhine reaches the North Sea. Engravings and particulars of this great work are soon to be published in "Engineering." The bridge has one great span of 492 feet, one of 262 feet, and 7 of 187 feet each. The total length is 2,181 feet, and the contract price was £153,000. The girders spanning the great opening are 515 feet long, and 65 feet 6 inches deep.

The railway bridge over the Danube at Vienna will be an important work; comprising 5 spans of lattice girders of 262 feet opening each, and 4 other spans of 112 feet.

The Dutch Government will eventually construct, although they have not yet commenced, the great railway bridge over the main outlet of the Rhine at Moerdyk, between Antwerp and Rotterdam. This bridge will be a mile in length, and it has been proposed to make it in spans of 400 feet each. "Engineering" says :—As compared with such works, there are at present no hopeful schemes in England. Mr. Fowler's proposed great $2\frac{1}{2}$ mile bridge over the Severn, with its 600 feet central span, its 245 feet side spans, its thirty 150 feet spans, its twenty-six 120 feet spans, and its twenty-seven 90 feet spans, is still in abeyance, but it will be built *some time*. It is true we have the frantic Boutet seeking to excite capital for the construction of a 10-span bridge across the English Channel, with openings *only* 3,282 yards (!) in the clear, and it is such schemes, stamped with ignorance, impudence, and infatuation, that sicken the heart and madden the brain of the true engineer.

Harbors and Docks.—A large number of important harbor and dock works were completed last year. The Millwall Docks, by Mr. John Fowler and Mr. William Wilson, comprise 2 basins of 25 acres and $10\frac{1}{2}$ acres respectively, and a graving dock 402 feet long, and 86 feet wide, with an entrance of 65 feet. The graving dock has "bilge carriages," so arranged as to be run under a ship to keep her keel off the ground. These docks have 28 feet of water and 7,700 feet of quay frontage. This work, replete with the latest inventions necessary to afford the most perfect and complete accommodation for vessels, is furnished throughout with the Elswick hydraulic machinery for which Sir William Armstrong & Co. have become famous. A very fine specimen of the telescope bridge is found here, of probably 80 feet span, and which, actuated by water pressure, rises from its bearings and slides endways from off its span, when called on, with incredible facility.

The Sutherland Docks have been extended by Mr. Thomas Meik. The new Hudson basin is 11 acres in extent ; the new outer harbor has been enlarged to 28 acres. The Leith Docks, by Mr. George Robertson, are nearly completed; also the new Western Dock at Hull, by Mr. John Hawkshaw. The Tyne Improvement Works, by Mr. Ure, are progressing. About 4,000,000 tons of material are being dredged yearly, at a cost of rather more than 4d. per ton, and the whole yearly expenditure, including that upon the Great Tyne piers, is about £250,000. A large graving dock* is in course of construction at Hebburn, Gateshead.

The Admiralty works in progress at Chatham, under the direction of Colonel Clarke, will involve an outlay of £1,500,-

* See "Engineering," December.

000, and comprise the reclamation of St. Mary's Island, 300 acres in extent, the construction of 3 basins of respectively 22, 20, and 37 acres, the construction of large graving docks, slips for laying up frigates, etc., and an immense steam factory, 1,000 feet by 700 feet. The new dock in French Creek, Malta, is also progressing under the same direction.

Among proposed harbor works, the improvements at St. Helier's, Greenock, and Scarborough, have attracted the greatest attention among engineers. The Greenock works to be carried out, comprise a large basin, graving dock, extensive quays and warehouses, and special arrangements for shipping large quantities of coal. At Scarborough, the only work proposed is a pier, enclosing on one side a harbor larger and better than at present.

The Clyde Trustees have decided upon the construction of a graving dock of great size, viz., 503 feet long, 100 feet wide, and 30 feet deep, the entrance to be 83 feet wide. New harbor works are to be at once commenced at Aberdeen, and additional works are proposed at Dublin, at Newport, Cardiff, Llanelly, and at Porthcawl.

A new graving dock is building at Williamstown, Victoria. Its dimensions are to be 240 feet by 97 feet, with an entrance 80 feet wide.

Mr. Hawkshaw is constructing the Grand Canal to connect Amsterdam direct with the North Sea, so that ships from the Dutch capital will strike deep water a little to the north-west of Harlem, instead of beating miles out of their way around the Helder.

Nor should the works in progress at Havre be forgotten. The seven basins, as fine in their way as anything in Europe, are to be still further extended, and Messrs. I. C. Johnson & Co., of Gateshead-on-Tyne, have a contract with the French Government for 20,000 tons of Portland cement for these very works.

The Bermuda Floating Dock.—During the year a great iron floating dock, capable not only of taking the largest ship in the navy, but of careening her as well, has been completed for Bermuda. This structure is 381 feet long, 124 feet wide, 72 feet deep, and weighs 9,000 tons.* This is a double dock, one within the other, the sides or "double skins" being 20 feet apart, and enclosing respectively a load chamber, balance chamber, and air chamber. Water may be pumped into or from either of these chambers, so as to sink, lift, or tilt the dock as desired. This great work, designed by Colonel Clarke, of the Admiralty, was constructed and, after a slight hitch, successfully launched by Messrs. Campbell, Johnstone & Co., of North Woolwich.

The hydraulic graving dock, of which the first example was erected ten years ago at the Victoria Docks, is having new innings. One has just been sent out to Bombay. It has 36 hydraulic presses in all, each of a force of 400 tons, so that the total lifting power is 14,400 tons, and including its "saucer" it will thus lift the heaviest ship in the navy. Docks upon the same plan are spoken of for Jamaica, Malta, Brindisi, and Dundee.

The Holyhead Pier.—At Holyhead the great breakwater pier approaching completion, under Mr. Hawkshaw's auspices, is a noble specimen of marine engineering. It is constructed chiefly of stone taken from the mountain adjacent. The upper structure is of random-worked ashlar, presenting a flush face on the inside or harbor front, while on the sea face the material is quarry-faced, and, as far as may be practicable, set on end, giving it the appearance of being vertically ribbed. The base of the pier consists of *pierre perdue*, having a slope, of the angle of repose of the material, on the inside, while on the outside its form is that of a flat glacis, on which the sea must lash with intense fury, as the stone is much pulverized by its action, especially so in the gorge caused by the re-entering angle of the work. The plan of the work is that of a continuous wall, of 1½ mile long, zigzag, with 2 kants springing from the land at one end, and at the other resting in 13 fathoms of water at low tide. The upper structure carries a causeway of 38 feet wide, at 12 feet above which, on the seaside, there lies a banquette of 15 feet wide, floored with tooled limestone, and surmounted by a parapet of 4 feet high, of the same material and class of workmanship; which latter throughout appears to be as near perfection as possible. The high level is connected with the causeway by flights of stairs at intervals. From the base of the parapet on the external face

* See "Engineering," Oct. 19, 1866.

projects an echinus of 2 feet overhang, which, however it may add to the effect of the sectional profile, will surely meet with rough usage from the waves towards the extremity of the pier. Here green water of yards thickness comes over the parapet during a gale. The pier head is not yet completed. It will be, in plan, of a T section, the arms of the T showing a very slight projection, and rounded at the ends. The face-work here will be of granite blocks, of from 8 to 12 tons weight each; the hearting of red sandstone, of the same dimensions.

Port Saïd Harbor.—Extensive harbor works are, it is understood, to be undertaken, by an English company, at Alexandria. The works are to comprise a breakwater 3,250 feet long, a mole 1,650 feet long and 200 feet wide, 5,000 feet of quays, and a large dry dock. To the east of Alexandria is the new harbor of Port Saïd, at the northern end of the Suez Canal, the later now more than two-thirds finished. Port Saïd, now nearly completed, is formed by two piers, one 2,730 yards and the other 2,077 yards long, with an opening to the north-east. The harbor enclosed is nearly one square mile in extent, and the western pier is carried out into water 27 feet 6 inches deep. These piers have been formed of *béton* blocks, of which about 325,000 cubic yards only have been used. At the present rate of progress the canal itself will be finished in little more than a year, with a waterway 328 feet wide and 26 feet deep.* Apropos of harbor works on the Mediterranean, it may be added that there is a scheme to greatly extend the port of Marseilles. A paper, read some time since at the Institution of Civil Engineers, gave a most interesting account of the existing works there, which comprise, among other things, the loftiest and possibly the finest warehouses in Europe, unless we except the magnificent corn warehouses lately completed at Liverpool and at Birkenhead.

Growth of Philadelphia.—During 11 months in 1868, there were erected in Philadelphia 4,706 new buildings, and 1,173 buildings received alterations and additions. This city now contains above 800,000 inhabitants.

* See article on the Suez Canal on another page.

Protection of Large Buildings from Lightning.—This subject has been reported upon by M. Pouillet before the Paris Academy of Sciences. The "Engineer" gives a lengthened account of it. The first thing to be done is to establish a conductor, formed of square iron measuring four-fifths of an inch on the side, which shall pass without interruption over every portion of the building to be protected ; when the line is broken by towers, pavilions, or other erections, the conductor must pass up and down each, so as not to interrupt its course. This main conductor, of course, is modelled, as it were, to the form of the building, and often consists of several branches, particularly in the case of edifices like the Louvre, where there are several blocks of buildings perpendicular and parallel to each other ; it will also have many minor branches, for it must be placed in good communication with all the gutters, leads, and other large metallic surfaces on the roof. This great conductor or circuit must be placed in direct communication with a body of water, which is never wanting. Ten or a dozen wells might be dug to receive each a conductor leading from the main circuit. Each lightning-rod must be placed in perfect communication with the main circuit.

Cement to Resist Red Heat and Boiling Water.—To 4 or 5 parts of clay thoroughly dried and pulverized, add 2 parts of fine iron filings free from oxide, 1 part of peroxide of manganese, one-half of sea-salt, and one-half of borax. Mingle thoroughly, and render as fine as possible, then reduce to a thick paste with the necessary quantity of water, mixing thoroughly well. It must be used immediately. After application it should be exposed to warmth, gradually increasing almost to white heat. This cement is very hard, and presents complete resistance alike to red heat and boiling water.

Another Cement.—To equal parts of sifted peroxide of manganese and well pulverized zinc white, add a sufficient quantity of commercial soluble glass to form a thin paste. This mixture, when used immediately, forms a cement quite equal in hardness and resistance to that obtained by the first method.—*Blätter für Gewerbe.*

PUBLIC BUILDINGS.

HOSPITALS—THEIR REQUIREMENTS, ARRANGEMENT, AND VENTILATION.

Condensed from a paper before the Architectural Association by T. R. Smith, F. R. I. B. A., and from the ensuing discussion.

Hospitals are peculiarly a modern institution. While examples of many classes of structures suited to our modern ways, such as, for instance, houses, baths, theatres, and churches, abound in the remains of classic times, there are no Greek and Roman hospitals. The simple infirmary of a monastery is no example to us as to *scale;* and the vast establishments of the 16th and 17th centuries are not very valuable specimens of arrangement and detail.

When we remember the great cost and disturbance of domestic arrangements necessary to provide suitable air, light, quiet, medicine, food, and attendance to the sick in our houses, and reflect that the poor, and even the majority of the people, cannot provide nor afford these facilities, the necessity for *many* hospitals and of *good* hospitals with all these facilities that make the difference between life and death to so many of our fellow-creatures, becomes obvious.*

At the same time, so good an opportunity of studying disease is not to be neglected. Where some hundreds of sick are always collected, there the students of sickness and how to cure it ought to be, and in fact are found.

What a Hospital Must Provide for.—We have now the elements for understanding this question.

First. The inmates, or in-patients, that is, the sick who reside and are treated in the house. The rooms they live in are technically termed wards.

Secondly. The administration. This embraces medical officers, dressers, sisters, nurses, attendants, and the parts of the building appropriated to their use, and to cooking, stores, business offices, etc.

Thirdly. Out-patients. Those who come to the hospital periodically for advice and medicine, and the portions of the building where they are received, seen, and supplied.

Fourthly. The Medical School, that is, students and professors, and their lecture rooms, library, museum, dissecting room, etc., etc.

Requirements of Wards.—The most important part of a hospital is the wards. For economy of attendance it is practically found best to place from 20 to 30 beds in a ward; reserving, however, a few small wards where only 2 or 3 beds are receivable for special cases.

The most important provision for the sick which the architect can make in a hospital, is a supply of plenty of fresh air. This is the one consideration to which all others ought to give way. The patient ought to have plenty of air in his ward, and that air ought to be constantly renewed. This, according to all authorities, will promote his recovery more than any one thing, and will prevent his injuring his fellow-sufferers. Many diseases are directly communicable by atmosphere, and surgical cases vitiate the air of the room. The best authorities consider that each bed should have from 1,500 to 2,000 cubic feet of air space, and that the change of air, while, of course, not sufficiently rapid to create a draft or a breeze, should yet be sufficient to be felt as an air passing over the face and hands. The sick must not be so placed that the air to reach any bed must necessarily pass over any other, they must not be too many in one room; there must not be too many wards under one roof, nor too many stories of sick one above another, nor too ready access from one ward to another. And there must be clear passages between the beds and up and down the ward.

Next to air, light and cheerfulness are conducive to health. All these requirements are practically best met by wards that are long in proportion to their width, arranged so that one of the long sides shall have an aspect exactly or nearly south, with a row of beds at each side, placed with their heads to the wall, and a row of windows on each side. A width of over 20 feet, and under 30, averaging 25 feet, is the most useful; over 30 feet the ventilation becomes sluggish. Beds ought to be about 8 feet apart from centre to centre, and the height of the ward ought to be at least 15 feet. No bed should come in front of a window. A window to each 2 beds is the usual allowance, and the windows ought to go as

* Even in the large English schools it has been determined to make the hospitals in one ward, rather than in separate rooms.

nearly as possible to the ceiling, and to come down low enough for patients in bed to be able to look out of them.

VENTILATION is a subject upon which authorities in all countries differ. The best known and most followed English plan is having windows facing each other on the two sides of each ward, and keeping them almost constantly open. This is termed natural ventilation. For this purpose windows may be sash windows in several heights; often, however, they have in their height several casements, each hung at the bottom edge, and capable of opening back at the top, so that the incoming air shall be thrown upwards. These casements ought to be capable of being regulated with great nicety, and made to remain at whatever angle they are set. They should be glazed with thick plate glass to diminish the loss of heat that occurs at all window openings; or, better still, double glass, with perforated zinc, taking the place of some of the panes of glass.

But there is in this apparatus the means of killing patients as well as curing them; especially in a climate like ours. Window ventilation, especially where not tempered by wire gauze or perforated zinc, is often the cause of fatal or dangerous relapses. Patients suffering from kidney disease, bronchitis, or rheumatic fever, are certain to relapse if they get a chill. A greater degree of care is required where there are many surgical cases. The belief is therefore spreading, that an appliance for keeping up a supply of fresh air, warmed and moistened, and for drawing off foul air, ought to form part of a hospital ward, and ought to be equal to keeping the wards thoroughly aired in frosty or stormy weather, at night, or at any other time, when windows cannot be safely open.

In the warming and ventilation of the new St. Thomas's Hospital, in each ward there will be 3 open fire-places on the centre of the floor,* with a vertical tubular flue from each passing up to the ceiling, having an outer air-tube round. This will serve to carry off some of the vitiated air beyond what goes up the flue with the smoke. The architect has also supplied 4 foul air extraction flues, which meet in the roofs, and near the outlet of which a current is kept up by a coil of hot-water pipes, which will be always at work, as they are part of the system for supplying hot water night and day to each ward. As an auxiliary for cold weather, coils are introduced on the floor, and the boiler for working them is a separate one. Air inlets exist in the floor. These arrangements are quite distinct and disconnected for the different pavilions as though they were distinct buildings.

There are hospitals with ward windows at the ends only, or merely along one side, and one row of beds down the centre, or even double rows with an open arcade between them like the nave and aisle of a church. But the knowledge has been slowly and painfully obtained, that these forms of wards are all, for this climate at least, a mistake, for the reason solely that they are found more difficult to ventilate, and there seems no reason to believe that any material alteration will be made in the dimensions, proportions, or arrangement of a hospital ward, till we have first established, if ever it can be done, a perfect system of hospital ventilation.

PROVISION AGAINST INFECTION.—The ward ought to be so fitted and finished as to harbor neither vermin nor infection. Wall paper and wooden skirtings must be dispensed with. Ordinary plaster is porous, so is soft wood; common floors and walls are therefore liable to absorb insidious poisons. The floors, accordingly, ought to be of the hardest wood, such as oak, not tile, which is chilly to the feet, and ought then to be rubbed with beeswax and oil till all the pores are filled up, and the surface is smooth and hard, or else oiled and lacquered, as is the fashion in Berlin. The walls and ceilings ought to be of the hardest obtainable material, Parian cement being recommended as having the best surface for the purpose.

HEATING.—For the heating of hospital wards, English authorities concur in recommending open fires. The French frequently warm their hospitals as they do other public buildings, by a hot-air apparatus, and must thereby run a risk of diminishing the advantage of their excellent arrangements in other respects.

THE BUILDINGS ATTACHED TO THE WARD

* To prevent these fires from heating the nearest beds too much, the openings to the fire-places are made to look up and down the hall or ward.

should be as follows: The head nurse of each large ward requires a separate room with a window looking into the ward. A smaller room called a ward scullery is also required with a fire-place, hot and cold water, and a sink. At the opposite extremity of the ward are required a group of closets, and one or more baths, and a lavatory. The arrangement of the closets is most important; not only should each have direct ventilation, but there should be a cross-current of air traversing the passage between the ward and the closets, in order, if possible, to prevent effluvium from coming into the ward. There ought not to be fewer closets than 1 to every 10 patients. Somewhere near the ward, but not in it, there ought to be a small lift, on which the patient's food, technically termed the diets, is brought up from the kitchen corridor, and it is usual to provide both a dust shaft and a foul linen shaft, from outside each ward to the basement. A large lift, capable of taking a patient and his bed and an attendant, ought also to be provided in each block of wards.

These, and no other rooms, ought to be appended to each ward. Convalescent rooms where they are introduced ought to be elsewhere.

The Series of Wards.—How are they to be arranged so as to make one large institution? From considerations of economy, especially in cities, we place them one above another; but this soon reaches a limit, and is objected to entirely by Miss Nightingale and others It is agreed on all hands, that it is advisable not to put the sick into a story exactly on the level of the ground floor.

The modes in which wards have been arranged are very various, but there appears to be a general feeling that the best possible way has been now found out. Where only two wards on a floor constitute the hospital they are well arranged in a continuous line with a staircase in the middle; where a larger number of wards has to be provided on each story, they would now be arranged parallel to each other (so that all can have a sunny aspect), and at a very considerable distance apart. This is called the pavilion plan, or block system. Each pavilion is in fact the ward, with its appendages repeated as many times as there are to be stories, and has its own independent staircase. It is isolated from its neighbors by a space which ought to be enough to keep it almost all day clear of the shadow of adjoining pavilions, affording its windows all the air and sun they require, and it is connected to its fellows by a corridor on the lowest story only. A usual plan is to make these pavilions occupy two sides of a hollow square. The best known example is one of the Paris Hospitals, the Lariboisière.*

Other Departments and Buildings.—The principal entrance for in-patients, leading to a receiving room, should be well marked and readily accessible.

The out-patients require a simple but spacious and well-ventilated waiting room, with a separate entrance and vestibule. The adjoining physicians' and surgeons' rooms should also adjoin each other, and should have a good light. A dispensary for receiving prescriptions and issuing medicines through a window should be convenient to the waiting room. All these rooms should have closets. A casualty ward where persons not seriously injured may be attended to, should form a part of this department.

An operating room (a theatre in large hospitals) should be accessible to the various wards. It should have a northerly top light, and connect with a surgeon's room, and a small ward for patients who cannot at once be removed after operations.

The dissecting room should be lighted from the top, and specially well ventilated. It should adjoin a dead-house.

Rooms for the physicians and surgeons, and residences for other officers and attendants, should communicate with a corridor leading directly to the interior of the hospital. The number of personal attendants on the sick is, in the best hospitals, one to every seven or eight patients.

The kitchen should be removed from immediate contact with the wards and ordinary entrances, and yet should be accessible to marketmen and tradesmen. It should be surrounded by the necessary stores and offices, and should have a wine cellar and ice-house. At the same time it must be central, so that the "diets"

* This, and several of the best modern hospitals, are illustrated in the "Civil Engineer and Architect's Journal," May, 1863.

(cooked rations) may be quickly carried to the various wards by lifts.

Linen, bedding, and bandages require a separate department. So does the laundry.

In arranging these separate departments, one rule should especially be followed—that whatever goes into them should pass in a direct course from one end to the other, without being shifted back and forth.

A Medical School, in addition to bedside or clinical lectures, should usually be attached to large hospitals, and should consist of lecture rooms, rooms for experiments and preparations, professors' rooms, a library, and a museum.

Sites.—As to sites for hospitals, Miss Nightingale says unhesitatingly that they ought all to be in the country. Certain it is that a pure air and plenty of space are the most important of all conditions of recovery. The arguments against the country are—first, that such sites are out of reach of patients; secondly, that they are out of reach of doctors; and lastly, that they are out of reach of students. The site must be spacious, airy, dry, sunny. It should not if possible be in an overcrowded neighborhood, or with any nuisance near. A gravelly soil is preferable, and a sufficiently high elevation. A bed of concrete over the whole site is recommended as a good preventive against moisture; this has been done at St. Thomas's.

NEW SYSTEM OF SCIENTIFIC EDUCATION.

A new system of high scientific education has been adopted in the government schools of France. The following abstract of the system is from the Paris correspondence of the "Engineer":

The new scheme, which is founded on Imperial decrees only a very few weeks old, includes not only laboratories of education and of research, but also the creation of a practical high school or college of science (*Ecole Pratique de Hautes Etudes*). The main idea of the plan is bold, simple, and sensible, namely, the making the present educational staff and establishments available for the new institution. With the view to carry it out, the Government has introduced into its budget an augmentation of the salaries of professors in the superior schools and colleges, to come into operation from the year 1869, in recompense for the additional labor which will be demanded of them in giving class lectures in addition to their present public ones.

The new laboratories will be of two kinds, one for instruction the other for research, the former being as it were nurseries for, and supplying the professors with assistants for the latter. Such laboratories of research, of which three or four already exist in Paris, have, says the Minister, "enabled Germany to arrive at that great development of experimental science which we watch with so much uneasy sympathy."

The new school is not to be essentially a professional school, but a college for improvement. "The young man," says the report, "who feels within him the sacred flame at which, perhaps, genius may light its torch; he who has completed his general studies, or the spirit of which may be repugnant to him; he who is not tempted by the hopes of a lucrative calling, or who may be irresistibly attracted from a profession already acquired towards pure science, does not find in our present establishments all the means necessary to help him rapidly and surely to the object of his vocation." Besides books, collections, and general lectures, he wants precise directions, general council, or support, and the means of verifying by observation and experiment the facts which he has acquired. "Able professors," says the report, "often discover peculiar bents or capacities in their pupils, and in the case of chemistry during the last thirty years much has been done in the way of superior education, and the rank of France in the world of science has greatly benefited thereby. The object now is to supply the other branches of science with schools like that which has done so much for this science." The word "practical" must not be taken in its ordinary signification of industrial utility, but in the higher sense and as indicating that the eyes and hands require to be called into use to strengthen and extend the most delicate and highest conceptions of the scientific spirit. What are chemistry without manipulations, physics and physiology without experiments, or botany without herballising?"

The school is to be divided into four

sections, entitled:—Mathematics, physics and chemistry; natural history and physiology; and historical and philological science; and to these may be added hereafter a section for juridical studies. Of course a pupil may belong to all or several of the sections.

The school is open to all the world, without any limit as regards age, grade, or nationality, but all pupils must undergo a preliminary stage of three months or less, at the termination of which the director makes a report; they are then examined by a permanent commission which sends up a list to the Minister, with whom alone rests their nomination to the school. Pupils can only remain 3 years on the school list. All the private lectures and normal lessons of the professors are open to them as well as the laboratories of instruction; they are bound to furnish written essays, *précis*, and analyses on given subjects and works published in France or abroad, and to make researches in the libraries and museums on set subjects, and to report results in writing; and the pupils in the natural history section will take part in scientific excursions under the direction of the professors. No mention is made of fees, so that the education appears to be perfectly gratis; and moreover the Minister may, upon the recommendation of the superior council, allow an annual indemnity to the pupils of the school. The directors of the laboratories have also the power of recommending pupils who show great aptitude as their assistants, and the Minister has the power of awarding them indemnities. Each section of the school is placed under a commission of five members nominated for three years by the Minister of Public Instruction, and chosen by him from the list of directors of laboratories and studies, as the professors of the school are called. The directors of the laboratories and of studies will grant certificates to their pupils, and make annual reports to the commission, and after examination of these reports by the superior council the Minister will entrust successful pupils with missions and award medals, honorable mentions, subventions, or special recompenses.

The organization of the new school extends to the provinces, the directors of laboratories and studies connected with scientific establishments in the departments as well as the pupils to enjoy the same privileges as those of Paris.

LIQUIDS FOR HARDENING STEEL—TEMPERING COLORS.

From a new Treatise on Steel, translated from the French of M. H. C. Laudrin Jr., by A. A. Fesquet. Philadelphia, Henry Carey Baird, 1867.

Notwithstanding what has been said, and the so-called experience of some practical metallurgists, pure water is the best liquid for hardening steel. It is a mistake to believe, with the ancients, that certain waters are more adapted to this operation than others. The only difference lies in their temperature. A workman of Caen, M. Damesme, who has published a diffuse work on steel, has tried the hardening of steel in the juices of vegetables, and has ascertained that there is comparatively no advantage over hardening in water. Mercury has no other property than that of being cold, and of producing a hardness which can be obtained with water at the same temperature.

Tallow and oils, where carbon is one of the constituent elements, produce an imperfect hardening, but prevent a loss of carbon. When by overheating, steel has been burned and decarburized, the oils and fatty matters are useful, because they give back to the steel a part of the carbon lost in the fire. Some acids, such as sulphuric, are justly considered as imparting more hardness to steel, by dissolving a film of iron from the surface and exposing the carbon. As for urine, alcohol, brandy, and a thousand other liquids extolled by ignorant workmen, they are not worth as much as water, which has the advantage of being abundant everywhere, cheap, and adapted to all changes of temperature.

Some workmen heat the steel which is to be hardened, much above a cherry redness, allow it to cool slowly in the air, and wait until it has taken a certain color, previous to plunging it in water. This is a very bad practice, because by an excess of heat there is a loss of carbon, and an alteration of the steel, which has then large grains, and is without tenacity at the edges.

After hardening, the temper or hardness is drawn as required for different purposes by reheating—the color of the steel being the guide.

1. Being put upon burning fuel, the steel gradually heated becomes tarnished, yellow, and *straw yellow.*

2. The heat increasing, the color deepens, and reaches a gold yellow, *full yellow.*

3. Afterwards, the steel takes several shades, rapidly following and blending with each other ; they are purple, pigeon's throat, copper, *brown purple.*

4. These shades become deeper until they become *violet.*

5. Afterwards, they pass rapidly to indigo blue, *full blue*, *dark blue.*

6. This color becomes weaker, and gives a *sky blue* more or less pure.

7. The blue takes a greenish tint and produces shades which are gray and *sea-green.*

8. At last, the steel *reddens*, and will no longer give distinct colors.

The shades of these eight colors, which are called tempering colors, and perfectly distinct, very apparent, and easy to recognize; but they take place only after hardening and on clean steal. The metal which has not been hardened, will not show these colors so plainly ; the shades are mingled, blended, and less in number.

The colors, during the tempering, are a sure guide for the workman, of the degree of hardness or tenacity he desires to obtain. Dark blue indicates a great tenacity, straw yellow produces a greater hardness, and is the tempering shade for razors. Bistouries, lancets, penknives, erasing knives, some scissors, and generally blades requiring body, are reheated to full yellow. The strong blades for table knives and gardening tools are tempered to a brown or purple brown. Purple is the proper color for large shears. Violet and dark blue are for springs ; with a violet color, the spring will be very elastic but brittle, a blue shade will make it very resisting. It is very difficult to break a spring reheated to the color of water; but its elasticity is a great deal lessened.

The hardened instruments are reheated in or upon a live fire, easily regulated, and without the help of bellows as far as practicable. An intelligent workman will cease blowing as soon as he perceives that the metal begins to change its color. The proper shade must come by itself without increasing the fire, and must be regular all over, before the piece is plunged in cold water. Sometimes this last dipping is omitted.

The small pieces, such as penknives, erasing knives, etc., rest upon a wire cloth put into the middle of the fire; when they have reached the proper color they are cooled in water.

A lancet requires a special tempering; the shank must be blue; from there the color will be first purple, next brown, and at the point, full yellow. These various shades upon one blade are a necessity, on account of the degree of hardness and tenacity required by this instrument. Full yellow will produce the proper sharpness, but would not be suitable to the rest of the blade, which, instead of hardness, must have tenacity and elasticity.

A good workman, willing to give the greatest perfection to an instrument, will be very careful when tempering it, in order to obtain the various shades which are necessary. A knife, for instance, must be brown purple at the cutting edge, purple in the middle, and sea green at the back, to unite the hardness of the cutting edge, with a certain amount of resistance which will prevent its breaking under a strain.

This is obtained by using certain precautions, and above all, by not going beyond the proper degree, because it is very difficult to retrace the steps. If the fire was too strong or irregular, part of the edge may be purple brown, while the other is only straw yellow; then, by pinching the blade between red-hot tongues, at the place which should be more heated, the temperature rises rapidly, and the instrument is brought up to the proper tempering point. Certain scraping and burnishing tools, and steels for sharpening, do not require any tempering, because they cannot be too hard.

The Rhode Island Locomotive Works are making 5 locomotives a month, and their capacity is to be doubled.

Lead Pencils, once really made of lead, are now chiefly made of the plumbago from the Alibert mines in Siberia.

ELECTRIC LIGHTS FOR LIGHT-HOUSES AND SHIPS.

By Ernest Saint Edme, of the Conservatory of Arts and Trades.

Translated from *Annales du Génie Civil*, September, 1868.

The Electric Light is nothing but the luminous arc formed between two carbon points fixed at the poles of a strong pile, or magneto-electric machine. It is due not to the combustion of the carbon points, but to the irradiation of their molecules, which fly continuously from the positive to the negative pole of the source of electricity. Hence, were there no combustion, that is, were the operation in a vacuum, the distance between the points being regulated according to the intensity of the current, there would be a continuous luminous arc, since the exact quantity of matter forming from the positive would arrive at the negative pole.

The function of a *regulator* of the electric light is, therefore, to correct mechanically the space between the carbon points, which results from their combustion, in air. The operation cannot be in a vacuum, for the glass envelopes cannot resist the heat due to the formation of the arc. Messieurs Staite and Petrie in England, and Léon Foucault in France, solved at the same time the question of photo-electric regulators; and to Foucault is due the first idea to make the electric current itself regulate the movement of the points. Since the first attempts to apply magneto-electric machines to produce light, the regulators exclusively used were the well-known ones of J. Dubosc, disposed to utilize the continuous currents; but the conditions of the apparatus were such that they could work with intermittent currents. A little later, when the regulator of Mons. Serren was coming into use, Mons. Joseph von Malderen, during a discussion, inquired of him whether he could overcome some of the defects of Dubosc's lamp; and he found that the principle of Serren's regulator was such that it could work with currents uncorrected. Thus it was a lucky chance that led to the discovery that the regulator of Serren, constructed like all others to be used with currents from the pile, could work with the uncorrected currents of the machines; but that which had no chance about it was the intelligence and perseverance of Malderen, who comprehended that the difficulty came from the regulator; and that what one failed in, the other might perhaps accomplish.

Since then, each inventor had to transform his apparatus; and Foucault, just before his death in 1866, gave the last touch to one of his early models, and confided to Dubosc the task of realizing his idea. Serren's regulator was applied in the light-house at Cape la Hève, and Foucault's in the garden of the Exhibition. The latter excited doubts on account of the great precision required in fitting; but a trial of long duration proved the genius of its author, and his ability to reconcile delicacy and complexity with solidity.

Foucault undertook to make a regulator that should absolutely fulfil the two main conditions—the diminution of all the causes of extinguishment, and the fixity of the luminous point. The two principal causes of extinguishment are: the too great separation of the carbon points, and their accidental contact.

[The description of the apparatus would be scarcely intelligible without the engravings, which we have not time to prepare for this number; we therefore must refer those who are specially interested in the details to the *Annales du Génie Civil*, for September, 1868.]

This regulator, constructed by Dubosc, has since been arranged by him to work either with the pile or the magneto-electric machine, with the precision required; and it is sufficiently hardy for service in light-houses, ships, and operations under deep water.

Mons. Reynaud, director of the administration of light-houses, three years ago, made a complete report on the question of electric lighting on the coasts; and since then nothing of interest has appeared to add to that report. The following tables taken from it show that the cost of lighting by oil is dearer than by electricity, in the proportion of 580 to 79.

Light-house with Oil Light.

	Francs.
Apparatus, with armature	37,940
Mechanical lamps, 3	2,100
Revolving machine	3,200
Furniture	900
Lantern, with glass, etc.	20,400
Setting up	3,900
	68,440

Annual cost for 4,000 hours of lighting.

	Francs.
Interest and wear, 10 per cent	6,844
Annual expenses	7,973
	14,817

Which, divided by 4,000, gives 3.7 as the cost per hour.

The intensity of the light sent to the horizon, is about equal to 630 Carcel burners: the cost per unit of light equal to that of a Carcel burner, is therefore .58 francs.

Light-house with Electric Light.

	Francs.
2 magneto-electric machines	16,000
2 steam engines and accessories	6,000
2 regulators and setting up	3,000
Lenticular apparatus	3,000
	28,000

Cost per hour for 4,000 hours per year.

	Francs.
Interest and wear	.70
Fuel for steam engines	.40
Wages for 2 firemen	.70
Wages for 2 watchmen	.50
Carbon crayons	.36
Oil, etc., for machinery	.13
	2.79

The mean intensity of the light sent towards the horizon, that is, taken outside of the apparatus, is equal to 3,500 Carcel burners, which gives as the cost of a Carcel unit of light sent to the horizon, $\frac{2.79}{3500}=$ .079 francs.

Against this immense advantage in favor of electric light there is the fact that the light from oil has more power to penetrate fog, being richer in red rays, than the electric light. In misty evenings one can see that the moon and gas lights have a red or orange tint, the blue rays being refracted, and unable to traverse the foggy atmosphere. Therefore, to make the electric lighting sure, it is necessary to have 2 machines, one of which will be kept ready for use in case of accident to the other; or in case of fog, when both will work together, and give double light. In this way the greater atmospheric resistance is overcome. This expedient is not possible with oil lamps; for we cannot double the flame of a lamp as we can double the electric current that flows between the carbon points.

Electric lighting in light-houses seems not to have made much progress since the report Mons. Reynaud; and the reasons of it are easy to be seen.

To transform existing light-houses, we must sacrifice the existing apparatus, for the sole advantage of increasing the light at any moment. Besides, it is doubtful whether all light-houses are large and strong enough for the accommodation of the new machinery; this is certainly the case with most of the light-houses on the coast. As to the light-houses of inferior order, it would be illusory to think of altering them. And other difficulties are inherent in electric lamps, which, however well designed, are subject to causes of derangement which render necessary the best mechanism; and the crayons, if impure, may scale, and cause interruptions; and these impurities might cause mistakes incompatible with the service of the light-house.

In conclusion, when a new light-house is to be built, it will be advantageous to adopt the electric light; but the importance of the question, relative to the general administration of light-houses, is much less than was at first supposed.

In 1863, in a notice of the applications of the electric light, we suggested the lighting of vessels by it. The maritime exhibition at Havre shows that our suggestion has been considered, at least in principle. In the point of view of lighting the course of a ship, no one will deny that the oil lantern is insufficient to prevent collisions at night; while the electric lantern would illumine the air all around, and the rocking of the vessel would cause such changes of light as would attract the notice of the men on other vessels. When we consider the whole cost of a ship, that of electric engines is insignificant; 2 or 3 horse-power will work a magneto-electric machine. And the electric light will serve other purposes on board a ship. Recent experiments have shown that it would be possible to assist a ship in her course by dazzling the steersman by a jet of light, when an oil lantern would not be seen by him.

It can also be used to light under water; an application that concerns the repairs of the sheathing and hulls of vessels, the finding of lost articles, and the catching of fish. The fish are confused by the light, and then easily caught. Mons. Dubosc exhibits a specimen lantern well fitted to enclose an electric lamp. The conducting wires are connected so that there is no chance for water to leak into the lantern. This apparatus can, without fear of too high pressure, be lowered to great depth in the sea.

View from a Balloon.—The view over London, in ascending 2,000 feet, is thus described by the "London News":—The earth and its dwelling-places, its trees, its roads, its rivers, drop slowly down and resolve themselves into a clearly defined, widely spreading map. The steamers plying on the Thames recalled the toy-boats at the Polytechnic; the black ants rushing busily to and fro in the barren space immediately below were schoolboys in a playground a few minutes since; the strips of drab tape stretching their devious courses to right and left are roads; the squares and oblong green patches with dark borders, fields; and that large table upon which a game of dominoes is apparently being played is Brompton Cemetery; and it is its profusion of white tombstones, some flat, some upright, which are recalling the old game. There seems a mighty stir among the pigmies below, and huzzahs which become faint in the distance, but are never quite lost, come up to us cheerily. The small boxes drawn by ants, into which cabs and omnibuses have resolved themselves, twine their way along the strips of drab tape, and almost arouse wonder by never deviating from their path.

Sulphocyanide of Ammonium. — At the last meeting of the British Association, Dr. Phipson read a paper on this subject, in which he pointed out a fact of some importance to agriculturists, viz.: that for many years past the ordinary sulphate of ammonia manufactured in gas works by neutralizing gas liquor with sulphuric acid contained small quantities of sulphocyanide of ammonium, say from 2 per cent. to 4 per cent. ; but latterly many specimens of commercial sulphate of ammonia contained a very much larger proportion, some specimens yielding as much as even 75 per cent. of sulphocyanide. So that, in fact, the article might rather be named impure sulphocyanide of ammonium than sulphate of ammonia. The knowledge of this fact is of great importance to makers of chemical manures and farmers, inasmuch as only one-half of the nitrogen existing in sulphocyanide can be made available for manuring purposes.

Chemical Nature of Cast-Iron. — At the last meeting of the British Association the report on this subject by Dr. Matthiessen and Dr. Russell led to some discussion. It seems that though no less than 70 experiments were made in the production of pure metallic iron from its various compounds, the reporters had not yet succeeded in obtaining any iron perfectly free from sulphur. Dr. Mathiessen hoped, however, by continuing his researches, yet to obtain a perfectly pure sample of metallic iron. In the course of the discussion which followed, Mr. Sutton suggested that probably the presence of sulphur in iron was only another instance of the persistence of that element in the atmosphere, as shown by the experiments of Mr. W. F. Barrett, who first devised the method of detecting the presence of sulphur upon the surfaces of bodies exposed to the air by projecting upon them a flame of hydrogen, a magnificent blue flame resulting therefrom.

Boiler Explosions, having been attributed, from time to time, to every known agency of explosions, it is not singular that upon the discovery of nitro-glycerine, they should have been attributed to it—upon the following curious reasoning: Fatty matter in the water in a boiler, acts chemically on the steam, forming glycerine. When organic matter is present in the water, the chemical affinities will set free electricity, which generates ammonia—which mixed with moist air at a temperature 212° Fah. over water containing potash, produces the nitrate of potash. Glycerine and nitric acid readily combine chemically, the glycerine gives up a portion of its hydrogen and takes on a part of the oxygen, when they all combine into a new compound, nitro-glycerine, which has $2\frac{1}{2}$ times the specific gravity of water. Nobel's blasting oil is composed of glycerine, sulphuric acid, and the nitrate of potash. Nitro-glycerine being insoluble in water, and having greater specific gravity, it readily finds the bottom of the boiler, where it would remain were it not for the sudden rise of temperature. It is not explosive at 212° Fah., but at 360° Fah. (which it soon attains in contact with the boiler plate), explodes with 13 times the force of gunpowder. Hence those terrific and unaccountable explosions that so often take place when the boiler contains its maximum of water. Finally, at least 90 per cent. of all the terrific disasters on our western rivers have occurred in the spring of the year, when the rivers were full of surface water containing organic matter, fats or oils, potash, and sulphur; or they blew up at or near the levee of some city, where they had taken on a supply of water contaminated with sewerage, containing the very elements of destruction.

As the *Scientific American* suggests, all the elements of gunpowder also exist in river water, and gunpowder is, therefore, as likely a cause of boiler explosions as nitro-glycerine.

AN ENGLISH EXPRESS LOCOMOTIVE.

The following are the principal dimensions of the latest style of passenger engine on the Great Northern Railway. The engine has a pair of leading and a pair of trailing wheels, a pair of drivers nearly in the centre, and inside cylinders —the old-fashioned English engine, without modern improvements in the distribution of weight and strain, but well-proportioned in detail:

	Ft.	in.
Boiler:		
Diameter of barrel, inside smallest plate..	3	9½
" " " largest " .	3	11½
Length of barrel	10	2
Length of inside firebox	4	8¾
Width " "	3	5
Height " " at front	5	9¼
" " " at back	5	3¼
Thickness of barrel	0	0½
Thickness of smokebox tube plate	0	0¾
Thickness of firebox plates ½ in., except tube plates, which is ⅞ in. thick at the upper part, and thinned to ½ in. below the tubes.		
Number of tubes, 192.		
Length " between tube-plates	10	5⅞
Diameter " outside	0	1¾
Thickness " at firebox end No. 12 W.G.		
" " " " " 14 "		
Length of smokebox inside	2	5½
Diameter of chimney inside at top	1	6¼
" " " at bottom	1	0¾
Height of chimney above top of smokebox.	3	10

Heating surface:

Tubes (outside)	922¼	square feet.
Firebox	89⅓	"
Total	1011¾	
Firegrate area.	16.4	square feet.

Wheels and Axles:		
Diameter of driving wheels	7	1
" leading "	4	1
" trailing "	4	1
Distance between centres of leading and driving wheels	9	6
Distance between centres of driving and trailing wheels	7	6
Total wheel-base	17	0
Bearings of Driving Axles:		
Diameter	0	7
Length	0	7
Bearings of Leading and Trailing Axles:		
Diameter	0	5
Length	0	10
Diameter of axles at centre	0	5
Cylinders:		
Diameter	1	5
Stroke	2	0
Length of ports	1	2

The steam pressure carried is 130 pounds; the tractive force about 7,000 pounds; the regular speed 44 miles per hour, exclusive of stops. The tyres, axle-box guides, crank axle, guide bars, and piston-rods are of steel. The engine is fully illustrated in "Engineering," Oct. 9.

THE PHŒNIX MILLS, at Seneca Falls, N. Y., are the largest of their kind in this State. They comprise 3 buildings of the following dimensions: 200 by 70 feet, 150 by 50, and 120 by 65, with a warehouse 200 by 45, They contain 26 sets of woollen machinery of the most improved patterns. The working force of the mills is 1,000 hands.

OLD AND NEW WAYS OF BREAD-MAKING.

From the "American Artisan."

There is probably no substance used for food that has been made from a greater diversity of materials or by a greater variety of ways than bread, and very few which possess greater elements of interest to the general reader or the student of practical science.

It is believed that the earliest loaves were made at a period anterior to the invention of even the oldest grinding or pulverizing devices, by simply soaking grain in water until it became soft and pulpy and then pressing it into cakes, which were baked in the camp-fire embers where the rude and wandering tribes pitched their tents each night. It was but a slight advance on this to bray or pound the wheat, millet, or other grain in a mortar, and, after moistening the powdered mass, spreading it upon a hot surface to bake, or placing it wrapped in leaves in the hot ashes for the same purpose; yet this, almost the first and primitive method of bread-making, has obtained, with a simple change in the mode of pulverizing, to this day. When the Hebrews dwelt in the land of Goshen they baked the *huggoth*, or little cakes of unleavened bread, under the ashes or upon the hearth. In recent times the far-famed oat-cakes of Scotland have been made by wetting the coarsely bruised or powdered oats with water having a little salt dissolved therein, and after rolling the mass into a thin sheet placing it before the fire. Bannocks are said to be made in the same way in India, and in our own country bruised corn-meal spread wet upon a shingle, placed aslant in front of the hearthstone fire, constituted the johnny-cake that made the greater part of the pioneer's daily fare. The method of baking under the ashes is still followed by the women in Bulgaria when bread must be made in haste, so as to meet the wants of travellers; and the hoe-cake of the South owes its charcoal crust to the same process. The making of bread is also characterized by the unique nature of the materials used; for instance, the Laplanders, having no grain, make a kind of bread of dried and pulverized fishes and the inner bark of the pine-tree, and in Sweden and Norway the wood of beech and similar trees which contain no turpentine is sometimes converted into bread. This is done by macerating the wood in water, and boiling it to remove the soluble matter. The wood thus macerated, after being heated several times in a suitable oven, is reduced to a fine powder by grinding. It is asserted that this wood-flour much resembles that made from corn, having a yellowish color and being capable of fermentation on the addition of yeast, and furthermore producing loaves of uniform and spongy texture. This flour also yields by boiling in water a thick jelly something like that made from wheat-starch. Pulverized pine bark is very often mingled with rye-flour in Northern Europe.

The bread made according to the simple methods above described may all be classed as unleavened bread, but the use of barm for making raised bread was known as far back as the time of Moses; and its employment passed from Egypt to Greece and Italy, and afterwards to all the northern nations conquered by Roman arms. No other means of making light or raised bread were ever known until within a comparatively recent period, when the same spirit of progress that revolutionized other departments of industry led to improvements in the art and mystery of making the staff of life. A mention of some of these last may be of interest.

Aside from convenience in the process of making, one great object sought to be secured by the recent methods is to obviate the loss resulting from the fermentation produced by yeast, and which has been variously estimated at from 2 to 10 per cent. of the entire weight of flour. To effect this object the bi-carbonate of soda and hydrochloric acid have been sometimes brought into use, there being intimately incorporated with every 4 pounds of flour employed 320 grains of the powdered bi-carbonate. To the flour thus prepared is added a solution composed of 300 grains of common salt, $6\frac{1}{2}$ fluid ounces of hydrochloric acid, and 35 ounces of water. The dough being kneaded is placed in the oven for baking in the ordinary manner. The acid combines with the soda of the bi-carbonate, converting it into common salt which is left in the bread, and disengages carbonic acid which puffs or swells it up in the same way that the carbonic acid liberated by the action of leaven brings about the same end. Another plan, most frequently adopted in making rusk, gingerbread, etc., involves the use of the sesqui-carbonate of ammonia, which, when the dough is heated, is converted wholly into a gas and passes off, leaving the bread in the form of a light spongy mass.

There is also a different plan of making what is known as aërated bread, in which the dough is placed in a box, and mixed by machinery with water charged with carbonic acid. When the dough is taken from the box where it is thus mixed under pressure, the carbonic acid escapes from the water and "raises" the bread, so that by this means not only is all loss of flour prevented, but the process, instead of requiring 8 or 10 hours, as by the common mode, may be completed in 30 minutes.

TELEGRAPH ENGINEERING IN 1868.

The progress of telegraphy during the past year has not been distinguished by any remarkable invention, and generally telegraphic extensions in this country have been checked by the contemplated assumption of the telegraphs by the Government. Messrs. Siemens have projected and commenced, in connection with our North Sea cables, an extended aërial telegraph through Prussia, Russia, and Persia, to join our Indian lines at Teheran, and though rival interests are striving very hard to cry down this route in favor of submarine lines through the Mediterranean and Red Sea, we have no doubt that the known ability of the contractors, and the manifest superiority of a well-constructed land line over the uncertain durability of a submarine cable, will make this telegraph the favorite "silent highway" to the East

Immense stimulus has been given to submarine telegraphy. There are more miles of cables in construction at the present moment than at any previous period of telegraphic history, and during the past year new cables have been submerged—between Malta and Alexandria, 900 miles; between Sunderland and Denmark, 340 miles, and between Florida and Cuba, 110 miles—though this last is not yet completed, owing to the expedition running short of cable. Sir Charles Bright is now engaged in completing his difficult task. The Danish cable is remarkable for being the first cable of any length constructed with Hooper's insulated core, and 500 miles of cable of the same material are now coiled in the tanks at Henley's works, waiting submersion in the Persian Gulf. The largest submarine project of modern days, the French Atlantic cable, is making rapid strides at the gutta-percha works and at the telegraph construction works at Woolwich. It is expected to be laid in August. It consists of 3,047 miles of rope, and it will be submerged from the same ship and by the same experienced hands that were engaged over the previous cables.

During the year Professor Wheatstone received the just reward of a knighthood for his numerous and beautiful inventions in telegraphy.

The Atlantic cable broke near Newfoundland, and was readily repaired. This is the second time such an accident has occurred. Many other such accidents have happened during the year to other cables, including the Persian Gulf, the Malta and Alexandria, the Dunwich and Zandvoort, the Lowestoft and Zandvoort, the Sicilian and Algerian, etc. The maintenance of submarine cables has become an important and valuable branch of the engineering profession, and the experience of our engineers has shown that repairs to cables are practicable in all depths. Considerable confidence in such enterprises has been engendered, and the public are becoming far more liberal in their contributions towards this vast field for investment. China and Australia cannot long remain beyond the pale of the electric spark.

The all-absorbing domestic question of the day is the purchase of the telegraphs by the State. This is expected to be completed in June. The telegraphs will pass to the control of the active executive of the Post-office, and the public will be great gainers by the exchange. How the professional branch is to profit or suffer remains to be seen.—*Engineering.*

WATER-POWER in Maine, according to a State report, consists of above 2,000 different "privileges" of an aggregate of 300,000 to 600,000 horse-power.

Ship Canal from Oswego to Albany.—It is proposed to construct a ship canal from Oswego to Albany by enlarging the Erie Canal from Albany to Oneida Lake, thence along the head of the lake and down the Oswego river. The lockage is 230 feet. With this canal, vessels loaded with grain could sail from Chicago to Liverpool by way of New York, avoiding the difficult navigation of the St. Lawrence river.

Furniture-making in Italy.—The Italian cities were famous in the middle ages, but not more famous than at present, for the production of furniture and house and church decoration in wood, not only in large quantities, but of light and tasteful designs. The principal modern works of Barbetti, at Florence, employ about 100 workmen, and turn out a value of half a million dollars per annum. At Milan there are 30 smaller manufactories, employing some 250 men. The more beautiful of their productions are in carved woods and in marqueterie work, inlaid with metal and enriched with ormolu or colored stones, or miniatures and pictures in majolica. In various parts of the province of Milan this manufacture gives employment to 350 families. Here, as well as in the Venetian provinces and about Naples, much cheap as well as costly furniture is produced. At the principal works in Florence, Milan, Turin, and Naples, wood-working machines driven by steam are considerably employed.

Winans' Cigar Steamships. — However opposed the principles of Messrs. Winans' construction may be to the general practice, it should appear that they have not been arrived at without long and costly preliminary experiment. The "London Times" details experiments made by Mr. Winans long since, in Baltimore, with various forms of hull and frictional surfaces, and states that Mr. Winans' plans are soon to be tested on the large scale of ocean navigation.

Australian Coal, equal to the English North Country coal, is worth 7s. to 9s. per ton at Sydney, the mines being 5 to 7 hours distant, near the coast.

WORKING PLANT AND APPLIANCES.

From "The Building News."

Human invention and ingenuity are ever on the stretch to keep pace with the contingencies that are daily and hourly occurring, and are the inseparable attendants of an age of reason, enlightenment, and national education. No sooner is one improvement patented and given to the public than another springs up superior to its predecessor, and after that another, and so on until man's inventive faculties are racked and the powers of imagination strained to the utmost to meet the ever-increasing demands.

Notwithstanding that the aid of machinery has been called largely into requisition in the construction of engineering and architectural works, yet many of the processes and operations still continue to be carried on by manual labor. Earthwork is still nearly universally performed by hand. The old system of laying down temporary rails, filling the "lorries," and tipping them over the "tip head," is still practised, and will be for a long period to come. Where the excavation takes the shape of a tunnel, special machines are used, as in the case of Mont Cenis, which is an example upon the largest and most successful scale that has ever been attempted. A marked improvement was visible in the construction of engines, movable cranes, and other mechanical appliances for raising loads at the recent "Exposition," in comparison with the specimens exhibited at previous international displays; they were much simpler in construction, better finished with respect to fitting and workmanship, more practical in design, less costly, and better adapted for rapid manipulation, and less likely to cause accidents and mishaps among those working them.

Except in comparatively insignificant instances, the old system of scaffolding for house building is completely obsolete. Contrast the methods at present employed in the erection of the new mansions on the estate of the Marquis of Westminster with the more ancient system, wherein round larch and fir poles and rope lashings formed the prominent features. We replace manual labor in what might be termed the transference of materials by the agency of movable cranes running upon strong timber traverses; and in this respect our system, as a whole, is superior to that of our French neighbors. There is no country where the erection of buildings, so far as modern inventions and conveniencies are concerned, has made so little progress as France. Notwithstanding that there is an abundance of more favorable appliances at hand, she continues to employ the ancient methods in spite of their slowness and cost.

One especial point in which there is a marked distinction between us and continental nations is in the substitution of iron for timber. Among ourselves this is now almost universal. An engineer would never dream of erecting a timber bridge except upon a scale of the most trifling character, nor, in fact, were it intended for railway traffic, would the Board of Trade sanction it. Cast and wrought-iron joists and beams are now the ordinary supports in warehouses and large buildings, to the almost entire exclusion of timber. The case is otherwise in France, where heavy balks are still employed in situations that we should now never think of their occupying. Recently iron wire has been used there with great success instead of ropes for scaffold fastenings. From very early times the Italians have been in the habit of adopting a peculiar description of scaffolding in which very short timbers are used, and the erection of which is carried on with extreme rapidity and considerable solidity. It is quite possible that if this system were modernized, and received the benefit of all the recent improvements and modifications, it might prove a very valuable one.

It might be supposed, from what has been stated respecting the substitution of iron for timber, that the trade of the carpenter had declined, and had, in fact, become merged in that of the smith. To some extent this is probably true, but not to a degree sufficient to affect the absolute earnings of the former. Permanent iron constructions of the present day demand an amount of carpenter's work for temporary purposes, far exceeding what was required for the permanent timber erections of bygone times. Let any one take a glance at the forest of piles, uprights, horizontal trussing, bracing, strutting, and centering, that obstruct the river at Blackfriars, and it will be more than sufficient to assure them that timber and carpentry still play a very considerable part in engineering and architectural structures.

Machinery has been established on the most improved system and on the most extensive scale for fashioning the timber-work intended for the interiors of houses; sawing, planing, mortising, tenoning, and all the other operations once performed solely by hand labor, are now accomplished by the agency of machines. It is rather curious that the principal railway terminus in Munich was one of the first instances abroad where all the timbers were prepared by machinery. Germany and our own country were the two foremost in availing themselves of the aid of steam power for this purpose.

The real merit of substitution of machinery for manual labor is undoubtedly due to the Americans, and in their case was a practical illustration of the old adage, "Necessity is the mother of invention." From a scarcity of manual labor, an inconvenience that all young countries suffer from, she was obliged to invent some means of accomplishing by machine power what was effected in more populous countries by hand labor. It is often said that the Americans invent, but we improve, and there is much truth in the remark. The reason is easily found, and the validity of the observation confirmed. The Americans have not the time to perfect any invention; they are daily, almost hourly, in want of it, and are compelled to utilize it before it has received that finish and those nice adjustments which in reality constitute the whole mechanical beauty of the machine. When the crude material comes to us we have leisure to examine it and it therefore receives from us that remodelling and final improvement which the urgency of the case did not admit of in the land of its birth.

Silsby's Fire Engine Works at Seneca Falls, N. Y., comprise 2 machine shops, 120 by 45, and 60 by 45, a foundry 90 by 50, a smith shop 75 by 50, a boiler shop 40 by 40, a paint shop, brass foundry, etc. They employ 160 men, and have built over 200 steam fire engines, besides various steam and pumping machines and hydraulic fittings. The Silsby pumps are rotatory instead of reciprocating.

THE IRON WORKS OF LE CREUSOT.

Condensed from the Correspondence of the "Mining Journal."

Few travellers through Burgundy, and more especially that portion of it purple in the summer's prime with the luscious fruit of the vine, would imagine that it has its black country. But a cloud of smoke persistently hangs over a portion of it—smoke from the iron works of Le Creusot, which, from the small proportions of a local forge, set up in 1769, have grown to be among the most important and extensive in Europe.

The best and easiest route to Le Creusot is by the railway which branches from the Paris and Lyons line a little south of Beaune, to Montchanin, and from thence by another line communicating with Nevers, which passes close to the works. Le Creusot now has a population exceeding 25,000 souls, all more or less connected with the works. In 1782 Le Creusot bore the name of Charbonnières, given to it in consequence of the discovery of coal near the village and close to the surface of the ground. The discovery having been communicated to Louis XVI. a company was formed, under his patronage, to work the mine; and as laborers were scarce, the king placed a regiment of soldiers at the disposal of Gauthey, engineer-in-chief to the States of Burgundy, who was appointed to open the mine. Shortly after a steam engine, constructed by Watt, was brought over from England, the cylinder of which is carefully preserved as an interesting relic. By means of this engine considerable quantities of coal were raised, and the almost simultaneous discovery of iron ore near the coal gave a fresh stimulus to the company. By order of Louis XVI. and on his death by that of the chiefs of the revolution, a great number of cannon and cannon-balls were cast here ; and the hill where the guns were proved and tried was called Les Boulets, by which name it is still known. After the revolution Le Creusot passed into the hands of the brothers Chagot, under whose direction various iron works were erected and all the gas-pipes for Paris made. In 1826 the above gentlemen disposed of the works to an English company—Manby and Wilson—for the sum of 2,620,000 frs. But the concern did not prosper in their hands—the company collapsed; and in 1837 the establishment was purchased by the Brothers Schneider, one of whom had been long engaged in commerce in Paris, while the other had been trained among the forges of the Ardennes. An unfortunate accident terminated the life of the elder of those brothers in 1845, since which period the management has been in the hands of M. Eugène Schneider (the well-known President of the French Corps Législatif), who has developed its resources to their present gigantic proportions—how gigantic may be conceived from the fact that while in 1837 the workmen did not exceed 1,000, they now number 11,000.

The greater portion of the iron ore worked at Le Creusot is obtained from Mazenay, at the junction of Burgundy and Maconnais. This ore yields 28 per cent. of iron, and extends over a vast area. The vein, which in no place is more than 130 feet from the surface of the ground, averages 6½ feet in thickness. The present annual yield is 262,000 tons. The ore is conveyed by a special railway to Le Creusot, where it is passed through enormous blast-furnaces of the most approved construction. Large as is the supply of iron ore from Mazenay, it does not meet the requirements, and other mines feed these great works. Among these is the famous Algerian Mine of magnetic iron ore at Mokta-el-Hadid, which yields no less than 65 per cent. of excellent iron, and of which large quantities are now shipped to Dunkirk, where it is sold at 1*l.* 8s. 10d. per ton.

To meet the great and continually increasing demand for steel, enormous works for carrying on the Bessemer process are being erected, which, when completed, will extend the total area of the works to 357 acres. But perhaps the most impressive department of this establishment is that of the forges, contained in a shed covering no less than 29.65 acres, and containing 68 steam-hammers, 672 machines of various kinds, and 85 steam-engines.

With respect to steam-hammers, it is due to our neighbors to state that they claim the invention of this most useful machine for their countryman M. Mourdon, who took out a patent for its construction in April, 1842, whereas Mr. Nasmyth, to whom the invention is generally attributed, did not, as they say, take out his patent in England until June in the above year, having, moreover, visited Le Creusot between the above months.

The shed containing the workshops for the construction of locomotives, marine and the other steam-engines, iron bridges, pontoons, etc., is scarcely inferior in extent to that devoted to the forges. It contains 37 steam-hammers, and 567 machines of various kinds. Locomotives are building here for nearly all the States in Europe.

That the flourishing condition of Le Creusot is partly due to the enormous supplies of iron ore and coal at its very door is unquestionable; but credit must be also given to the admirable management prevalent throughout all the departments. Its large and continually increasing business must also be ascribed, in a great measure, to the fact that the wages of the skilled workmen are below those received by English operatives of the same class. According to the information communicated, the wages paid to plate-rollers is 10 frs. for 10 hours' labor, and the first-class workmen engaged on locomotives receive only 5 frs. The average daily wages of all the workmen is now 3 frs. 45 cents. Low as these wages are, compared with those paid to English artisans in our iron works, the prices of provisions at Le Creusot are such as to enable the operatives to live comfortably within their incomes. The rent of a house, containing 3 rooms, varies from 100 to 125 frs. per annum; and the average living expenses of a family consisting of 3 persons is stated to be 1 fr. 50 cents per day. Great facilities are given to the workmen to purchase the houses which they occupy. The average cost of these is 1,800 frs.; and at present 2,131 workmen own the houses in which they live. Several excellent, and almost gratuitous schools exist in the town, the payment exacted being only 75 cents. per head monthly. Boys are taught reading, writing, grammar, arithmetic, and drawing; and those who manifest intelligence, and a decided capacity for mechanics, are sent, at the expense of the company, to the High School of Arts and Métiers at Aix, from whence they are drafted to Le Creusot when their education is completed.

From a statistical document, it appears that during the 15 years ending 1865, out of the entire population only 632 persons were sentenced to punishments for crimes, and these were of very light nature. Drunkenness—that curse of our country—is very rarely seen at Le Creusot; and woman beating, which disgraces English working communities, is, it may be said, entirely unknown.

Mineral Wealth of Missouri.—There are three copper fields in Missouri. These extend through Franklin, Crawford, Dent, Shannon, Wayne, Madison, and Iron counties, and include 500,000 acres of copper lands. The practical geology, topography, surface signs, and ores discovered and mined in these copper fields, indicate that the repletion, or filling of these copper veins, is on a scale of magnitude corresponding to the iron-producing action that formed the Iron Mountains. No copper has been mined in Missouri since 1856.

There are 2,000,000 acres of lead fields in Missouri; 30,000 acres have been mined and yield $25,000,000 worth of lead. This lead was made from ore from "clay diggings," which is the croppings of veins in the rock.

The value of pig-iron made in Missouri in 1867 was about $1,000,000, lead $300,000; no copper, zinc or nickel. Value of pig-iron made in Pennsylvania in 1867, in round numbers, $30,000,000. Missouri contains a much richer character of iron ores than Pennsylvania, and ten times the quantity.—*Iron Age.*

The Petroleum Trade.—Philadelphia ships about half of the petroleum sent abroad from the United States. Pittsburgh is the principal market for the article west of the Alleghanies. From January 1st to November 14th of the year just past, Philadelphia exported 33,665,224 gallons of petroleum. In the same period, the exports from Boston amounted to 2,267,517, and from Portland 580,400 gallons. During the same period in 1867, the exports from Philadelphia to foreign ports were 25,621,005 gallons, showing an increase this year of upwards of 8,000,000.

CARBON IN STEEL.—Hardened steel leaves no carbonaceous residue on solution in muriatic or diluted sulphuric acids; unhardened steel also leaves none when dissolved at as high a heat as possible with exclusion of air; but it leaves such a residue when solution is not at first or at the proper time aided by heat. This residue is not dissolved by further heating.

—RINMAN *in Erdman's Journal.*

WOOD suitable for cabinet making and decoration, according to a report on the woods in the Paris Exhibition, exists in much larger quantities and of much greater variety than is generally supposed. But a small number of the hard and beautifully colored and variegated woods that are accessible in various countries, have been brought into use.

Another report magnifies the value of wood to the world, deprecates the reckless waste of timber in new countries, and advocates the enactment of better laws for the preservation of forests.

THE STRENGTH OF CORRUGATED IRON.

BY J. E. HART, C. E.

From the "Bombay Builder," August, 1868. With comments by Professor Rankine, from "The Engineer," November 13, 1868.

The following are the experiments on the transverse strength of corrugated iron, alluded to in a letter published in the May number of the above journal:

The iron experimented on was supplied by Messrs. Nicol & Co., Bombay, and supposed to be of the following gauges: 8 BWG, 10 BWG, 12 BWG, 16 BWG, 22 BWG. The sheets or plates were supported on trestles, and loaded in their middle by weights suspended in a scale pan. The bending action of the load was distributed along the transverse axis by a rigid bar of timber laid across the sheet at right angles to the corrugations, and the pressure of this bar was distributed to ridge and furrow by a layer of damp sand. Fastened to this bar by a cotter was a flat strip of steel, which, passing through a slot in the sheets, suspended a stirrup with an universal joint carrying a roughly made scale beam. The dimensions of the slot were three-fourths of an inch long by one-fourth of an inch wide.

The object of this arrangement was to obviate any unequal strain on one side or other of the sheets through the oscillations of the load in the scale pan. The tressles were movable along sleepers sunk in the ground, so that the bearings of the sheets could be altered at pleasure. The deflections were measured with a scale of 50ths of an inch, which was hung from the lower side of the sheets between silk threads stretched by weights between the tressles. The thicknesses of the sheets were measured with a scale of 100th of an inch, read off with a magnifying glass. The sheets broken were of various lengths in order to test the accuracy of the formula; for the same reason the bearings were made to vary; and in order that the comparison might be closer several of the broken sheets were again subjected to experiment. The constant, or modulus of rupture arrived at, is on the whole sufficiently uniform, and establishes fairly Professor Rankine's approximate formula for the moment of resistance of corrugated iron (see "Manual of Civil Engineering," chap. v., sec. iv., art. 375).

$$\frac{4}{15} f \frac{hbt}{a} \ldots$$

which equated with the bending moment for a central load gives—

$$\frac{4}{15} f_a h b t = \frac{W l}{4} \text{ whence}$$

$$f_a = \frac{15 \text{ W} l}{16 h b t}$$

by which formula the modulus of rupture fa is calculated.

In the formula :

W = The total load in pounds;
h = The height of the corrugations measured from ridge to furrow;
b and t = The breadth and thickness respectively of the sheets in inches;
l = The bearing or span between supports in inches.

The heights of the corrugations were found to be very unequal, not only in adjacent ridges and furrows, but also in different parts of the same furrow. The heights given in the data are the average of all across the sheet in the middle, as shown in the sketches of the section. The outer corrugations, unless the plate was expressly cut, were not of the full depth; and their heights were rejected as an element of strength. The thicknesses varied in different sheets of the same gauge, and also slightly in different parts of the same sheet. They were measured from a piece cut out of the sheet, and carefully filed true; in a few cases, however, did they correspond with the tabular value of the thickness of the supposed gauge of the sheets. The placing and removal of the loading was effected through the medium of a lever and screw-jack, which arrangement obviated any chance of a jar of the material from jerks or vibrations of the load. Every care was taken to avoid inaccuracy, either of observation or of result.

No. of experiment.	Description of Sheet.	Weight in Pounds.	Deflection in Inches.	Dimensions of Sheet and Remarks.
1	Gauge No. 22 (probably)...............	164	·60	t = .029 inches.
		220	.82	l = 60 inches.

Mean value of fa = 46682 from all experiments, or = 46916, omitting No. 10.

It appears from these experiments that the highest and lowest values of $f\ a$ are respectively 58,940 and 41,101; the former of these extreme values I would reject as open to suspicion, because of the great discrepancy between the breaking load of it, and its sister sheet (No. 11). The mean value of $f\ a$ from the remaining experiments would be, as nearly as might be, 46,000, and this may, I think, be adopted as its true value. Experiments 2, 2a, and 6, 6a, show that the strength varies inversely as the length, although a slight of increase of strength appears in the shorter sheets, which may be accounted for by the deflection being less. The breadth does not appear to influence the constant, so that we may assume the strength to vary as this dimension. The depth also of corrugation does not appear to influence the result other than directly; that is, however, a point that could only be examined by having similar sheets rolled of varying depths of corrugations. However, Experiments 5, 8, and 9, afford a comparison as far as it goes. Experiments 6, 7, 12, and 13, show that in narrow sheets the position of the side edge, whether in tension or compression, makes a difference. This would appear to be a necessary consequence of the laws of strength of materials, and it was observable that when the side edges of the plates were up, as in Experiment 7, the edges cripped early in the experiment; while when they were down, as in Experiment

6, they did not fail till later. All plates first showed symptoms of failure at the side edges. None of the plates gave way suddenly, but each sank slowly when the breaking weight had been reached. As a rule, they appeared to fail by the spreading of the corrugations at the middle, and did not crush at the tops of the ridges; on the contrary, when the sheet was allowed to sink till rupture of the material took place, fracture occurred by tearing of the furrow commencing from each side of the central slot, and proceeding towards the sides of the sheet at right angles to its length.

It is probable that had the sheet been prevented from spreading by strips riveted across it, as recommended by Professor Rankine, the constant would have increased in value. In bridges the adjoining sheets would act so as to oppose the spreading, and this may be looked upon as an element of strength. The results of the observations of the deflections seem to be uniform, but at present no deductions from them are made. The ultimate deflections were in a few instances observed as a matter of curiosity, but in most cases it was not possible to hit off the very extreme deflections. I find that the increased value of the constant or modulus of rupture derived from the preceding series of experiments will so considerably modify the conclusions of my former communication that it is desirable that I should revise some of my previous calculations, and I therefore venture to go over some of the ground again, connecting and enlargening some of the deductions I have already made.

REMARKS BY PROF. W. J. MACQUORN RANKINE.

1. Reference to Mr. Hart's Researches.—A valuable series of experiments by Mr. Hart, on the transverse strength and stiffness of corrugated iron, have been published in the "Bombay Builder" for August, 1868, and reprinted in "The Engineer" of the 10th October, 1866, page 298. Mr. Hart shows that the results of those experiments agree very fairly with a formula proposed by me a few years ago* for the breaking moment of a sheet of corrugated iron, viz:

$$\frac{Wl}{4}=\frac{4}{15}fhbt; \quad \cdot \cdot \quad (1)$$

* "Manual of Civil Engineering," page 543.

in which l denotes the span; W, the breaking load hung at the middle of the span; b, the breadth of the sheet, and t, its thickness; h the depth of the corrugations from ridge to furrow; and f the coefficient or modulus of rupture. Values of that coefficient are calculated by Mr. Hart from his experiments by means of the following formula:

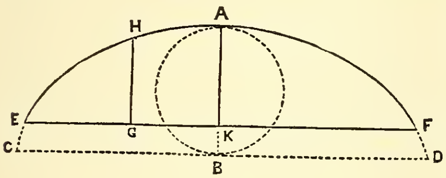
$$f=\frac{15}{16}\frac{Wl}{hbt}; \quad \cdot \cdot \cdot \cdot \cdot \quad (2)$$

and they are found to range from 41,100 pounds to 58,940 pound on the square inch; the mean value being about 46,000 pounds on the square inch. There can be no doubt then that the formula of Equation 1 may be safely used in practice to calculate the probable breaking load of sheets of corrugated iron of given dimensions; and that, in the absence of special experiments on the strength of the particular material that is used, the smallest of the values deduced from Mr. Hart's experiments, viz., 41,100 pounds on the square inch, may be taken as the modulus of rupture in the calculation.

2. Objects of this Communication.—The objects of the present communication are to explain the theoretical reasoning on which the formula of Equation 1 is founded, and the extent to which it is approximative; to determine, by the aid of Mr. Hart's experiments on breaking loads, values of the modulus of rupture according to a rule which gives a closer approximation; and to deduce, from his experiments on deflection, values of the modulus of elasticity of corrugated iron.

3. Assumption of a Cycloidal Cross Section.—The first step towards finding formulæ for the transverse stiffness and strength of a given piece of material, is to determine the geometrical moment of inertia of the transverse section relatively to a horizontal axis passing through its centre. In a sheet of corrugated iron, the transverse section is a narrow band of uniform width equal to the thickness of the sheet, and of a wavy figure, composed of a series of curved arcs, alternately above and below the horizontal axis of the section. These curved arcs usually approximate nearly in shape to arcs of circles; and no material error in practice is occasioned by assuming for

their figure any curve which does not greatly differ from a circular arc. A cycloidal arc is such a curve; and it has geometrical properties which cause the calculation of its moment of inertia to be a very simple process; therefore the figure of cross section of each of the ridges and furrows of the sheet of iron will be assumed to be a cycloidal arc, such as E A F in the figure; where C A D represents a complete cycloid, traced by a point in the circle A B, which rolls on the



straight base line C D; and the chord E F, parallel to C D, is drawn in such a position as to cut off an arc E A F, in which the depth A K bears to the breadth E F the same proportion as in the corrugations of the iron. That is to say, let a be the width of one corrugation, measured *from ridge to ridge*, and h (as before) the depth *from ridge to furrow;* then the chord and the depth of the cycloidal arc are respectively,

$$E F = \frac{a}{2}, \text{ and } A K = \frac{\ }{2}.$$

4. Geometrical Moment of Inertia.—One of the geometrical properties of the cycloid is as follows: The perpendicular distance H G, of any point H in the arc, from a chord E F parallel to the base line, varies proportionally to the product H E $\times$ H F of the two parts into which the arc E A F subtended by the chord is divided by the point H. To express this in algebraical symbols, let the arc A E = A F = c; the arc A H = s, the greatest ordinate A K $= \frac{h}{2}$ (as before); and the ordinate H G = y; then we have

$$y = \frac{h}{2} \cdot \frac{(c+s)\,(c-s)}{c^2} = \frac{h}{2}\left\{1 - \frac{s^2}{c^2}\right\}.$$

Let $d\,s$ denote an indefinitely short or elementary arc, situated close to the point h. Then the geometrical moment of inertia of $d\,s$ relatively to the axis E F is $y^2\,d\,s$; and that of the arc A E is expressed by the following integral:

$$\int_0^c y^2\,d\,s = \frac{h^2}{4}\int_0 d\,s. \left\{1 - \frac{s^2}{c^2}\right\}^2 = \frac{2\,h^2\,c}{15};$$

which, being divided by the length c of that arc, gives, for the *square of its radius of gyration,*

$$\frac{2\,h^2}{15}.$$

To find the geometrical moment of inertia of the cross section of a sheet of corrugated iron, the area of that section is to be multiplied by the preceding expression for the square of the radius of gyration: that is to say, let A be that area, and I the moment of inertia; then

$$I = \frac{2\,h^2\,A}{15} \quad \ldots\ldots \quad (3)$$

5. Formulæ for Strength and Stiffness.—The following are the well-known general formulæ for the modulus of rupture f, and modulus of elasticity or stiffness E, of a beam of uniform cross section loaded in the middle:

$$f = \frac{h}{2\,I} \cdot \frac{W\,l}{4}; \quad E = \frac{W'\,l^3}{48\,I\,v};$$

in which W is the breaking load; W′ any load not exceeding the limits within which the deflection increases in the simple ratio of the load; and v the deflection with the load W′. When the value of I given by Equation 3 is substituted in these formulæ, they become respectively as follows:

$$f = \frac{15\,W\,l}{16\,h\,A}; \quad \ldots\ldots \quad (4)$$

$$E = \frac{5\,W'\,l^3}{32\,h^2\,A\,v}. \quad \ldots\ldots \quad (5)$$

6. Determination of Sectional Area—Use of a Virtual Thickness.—A rough approximation to the sectional area of a sheet of corrugated iron may be obtained by simply multiplying together the breadth and thickness; that is, making

$$A = b\,t \quad \ldots\ldots \quad (6)$$

This is the approximation used in Equations 1 and 2. It always gives too small a value of the area; and hence, in using it to calculate the probable breaking load of a sheet of corrugated iron with a coefficient taken from experiments on iron in other forms, the errors to which it leads are always on the safe side; and this was the reason which induced me to adopt it in the book already referred to. It is obvious, on the other hand, that in calculating the modulus of rupture from experiment by means of the same approximation, the value obtained is greater than the actual stress on the material just in the same proportion in which the exact sectional area is greater than the approximate sectional area.

The length of the cycloidal arc E A=c in the figure is given with an error in defect which in no case exceeds $\frac{1}{400}$ part, by the approximate formula:

$$c = \frac{a}{4}\left(1 + \frac{8h^2}{3a^2}\right) \text{ nearly;}$$

from which it appears, that a second approximation to the sectional area of the sheet is given by the following formula:

$$= \left(1 + \frac{8h^2}{3a^2}\right) b\, t \quad . \quad . \quad . \quad . \quad (7)$$

Considering, however, how much more precisely the operation of weighing can be performed on a thin sheet of metal than that of measuring its thickness, it is obvious that by far the most accurate way of determining the sectional area of the sheet is to calculate it from the weight of a given horizontal area; and such, accordingly, is the method employed in a new reduction of the results of Mr. Hart's experiments. Mr. Hart gives, in each case, the weight in pounds per square foot of the sheet of corrugated iron experimented upon. That weight, in the following calculations, is divided by 40 (being the weight in pounds of a plate of iron a foot square and an inch thick), to give what may be called the *virtual thickness* of the corrugated iron; that is, the thickness of a *flat* sheet of iron of the heaviness of 480 pounds to the cubic foot, and of the same horizontal area and weight with the corrugated sheet. The product of the breadth and virtual thickness gives the sectional area: that is,

$$A = b\, t' \quad . \quad . \quad . \quad . \quad . \quad (8)$$

in which t' denotes the virtual thickness.

It may be remarked that the value of A, as given by Equation 8, is found in most, though not in all, of Mr. Hart's experiments to be somewhat greater than that given by Equation 7. It is probable that this may be caused by the iron being compressed in the process of rolling to a greater density than 480 pounds to the cubic foot. It is clear, nevertheless, that Equation 8 is the preferable formula; for in calculating the modulus of rupture and the modulus of stiffness, it eliminates the effect of such compression of the iron.

7. Method of Calculating the Modulus of Rupture.—In calculating corrected values of the modulus of rupture, the method followed has been to multiply each of the values given by Mr. Hart by the ratio $\left(\frac{t}{t'}\right)$ in which the measured thickness used in his calculations, is less than the virtual thickness used in mine. The results are given in the annexed table (A). They are computed to three places of figures only, as it would be useless to attempt greater precision. The difference between the extreme values is less, as compared with the mean value, than in the case of the values deduced by Equation 2 from the measured thicknesses, as the following statement shows:

Values in pounds on the square inch deduced from

	Measured thicknesses.	Virtual thicknesses.
Greatest	(No. 10) 58,940	(No. 10) 45,300
Least	(No. 3a) 41,101	(No. 9) 34,200
Difference	17,839	11,100
Mean	46,682	39,100

8. Method of Calculating the Modulus of Stiffness.—The values of the modulus of stiffness are calculated by means of Equations 5 and 8, from data selected from those parts of Mr. Hart's record of experiments in which the deflection increased in the simple ratio of the load, or nearly so. The results are given in the annexed table (B). They are computed to four places of figures only. The difference between the greatest and least values is, as compared with the mean value, a little less than the corresponding difference for the modulus of rupture, as the following statement shows:

	Pounds on the square inch.
Greatest value (No. 2)	23,290,000
Least value (No. 11)	17,760,000
Difference	5,530,000
Mean value	20,420,000

Mean in lineal metres of iron, weighing 7,690 kilogrammes to the cubic metre 1,867,000

9. Rules.—The following are the rules for practical purposes to which the results deduced from Mr. Hart's experiments in this communication lead:

I. Let b be the breadth of a sheet of corrugated iron, h the depth of the corrugations from ridge to furrow, and w the weight of an unit of the area of the sheet, as projected on a plane: to find the least probable *breaking moment*, M.

Calculate a virtual thickness, t', by the formula $t'=w \div k$; where k has the following values:

For w in pounds to the square foot, and t' in fractions of an inch; $k=40$.

For w in kilogrammes to the square metre, and t' in fractions of a metre; $k=7,690$.

Then

$$M=\frac{4}{15}fhbt'. \quad . \quad . \quad . \quad (9)$$

Least value of f;

For forces in pounds, dimensions in inches, and moments in inch-pounds. . 34,200

For forces in kilogrammes and dimensions in metres. . 24,000,000

II. Given, the intended least breaking moment M, the breadth b, and the depth of corrugation h, of a sheet of corrugated iron; to find the proper weight w of an unit of area;

$$w=kt'=\frac{15\,k\,M}{4fhb}. \quad . \quad . \quad (10)$$

Values of the factor

$$\frac{15k}{4f};$$

For w in pounds to the square foot, load in pounds, and dimensions in inches;

$$\frac{1}{228}=.00358;$$

For forces in kilogrammes and dimensions in metres;

$$\frac{1}{832}=.0012.$$

III. To find the *probable deflection* (v_1), *under half the breaking load*, of a given sheet of corrugated iron; l being the span.

$$v_1 = \frac{n''}{m'} \cdot \frac{f}{2\,\mathrm{E}} \cdot \frac{l^2}{4h}; \quad . \quad . \quad . \quad (11)$$

In which

$$\frac{f}{2\,\mathrm{E}} = .00096 = \frac{1}{1040}; \text{ and } \frac{n''}{m'}$$

has the following values:

Sheet loaded in middle of span $\frac{2}{3}$;

Sheet uniformly loaded, $\frac{5}{6}$.

The following later contribution to the "Bombay Builder" apparently concludes Mr. Hart's valuable paper on this subject:

Buckled plates—the invention and patent of R. Mallet, Esq., M. I. C. E.—are also an admirable substitute for wooden planking in the platforms of bridges, and have been extensively used in both England and India, the most notable instances being the Westminster and Soan bridges. They are square or rectangular plates domed in the centre, with a flat margin or "fillet" all round.

The versed sine or central rise is small, being about one twenty-fourth the greatest length of side. The fillet is from 2 inches to 6 inches wide, according to size of plate, etc. The material may be either iron or steel, and is protected from corrosion by a coating of some preservative composition, that recommended by the inventor being well-boiled coal-tar mixed with powdered caustic lime. In this the iron heated to black red (700° Fah.) is to be quenched. Steel plates will be half the weight of iron ones. Buckled plates possess certain advantages over corrugated sheets; for instance, they produce greater lateral stiffness in the platforms, and are said to be less perishable, owing to the fibre of the iron being less injured by the process of manufacture. They are lighter, and, of course, ought to be cheaper, because less material is used in an equal horizontal area of plate, the loss of plane surface in buckled plates being about one-seventieth of the original plate, while in corrugated sheets the loss is between one-fifth and one-fourth. On the other hand, to obtain full advantage of the strength of buckled plates, they must be supported all round. This leads to considerable expense in the arrangement of the girders and joists, and, except in iron structures, the requisite conditions cannot be readily obtained. Mr. Mallet states that the resistance of square buckled plates is directly as the thickness, and inversely as the clear bearing. That the resistance of a rectangular plate is nearly the same as that of a square plate whose side is equal the longer dimension of the oblong one, and that the longer edge should not be more than double the shorter. Also, that a plate fastened firmly on all its sides has double the strength of a plate merely supported all round; and if two opposite sides are wholly unsupported, its resistance is reduced as 8 to 5. In Rankine's "Civil Engineering," Section IV., Article 375, Division III., is the following formula for the resistance of a buckled plate.*

$$\mathrm{M} = \tfrac{4}{15} f_a\, l\, h\, t \quad . \quad . \quad . \quad . \quad .(20)$$

which is nearly the same as that given for corrugated iron. In this formula $f_a = 21{,}600$, l is the length of that section of plate at which the greatest bending moment is exerted; t, the thickness of the iron; h, the depth of curvature at the centre. If we suppose the plate to be supported at the ends only, the bending moment of the distributed loads is $= \frac{\mathrm{W}\,l}{8}$, hence the equation for the dimensions of the plate is

$$\frac{\mathrm{W}\,l}{8} = 5760\, l\, h\, t$$

$$\therefore \mathrm{W} = 46080\, h\, t \quad . \quad . \quad . \quad . \quad (21)$$

and if, as before, we take $w\,s = 200$, and since, as explained at equation 14, $\mathrm{W} = \mathrm{W}\ s\ \mathrm{L}\ \mathrm{B}$, therefore

$$t = \frac{200\,\mathrm{L\,B}}{46080\,h} = \frac{\mathrm{L\,B}}{230.4\,h} \quad . \quad . \quad . \quad (22)$$

If the factor of safety be 4, we have

$$t = \frac{\mathrm{L\,B}}{57.6\,h} \quad . \quad . \quad . \quad . \quad (23)$$

and if

$$h = \frac{l}{24} = \frac{\mathrm{L}}{2};$$

then

$$t = \frac{\mathrm{B}}{28.8} = .03473\ \mathrm{B} \quad . \quad . \quad . \quad (24)$$

* It is, I think, doubtful whether this formula will apply equally well for plates supported and fixed; but I have assumed that such is the case, basing my assumption on the treatment of the analogous case of beams fixed at both ends by the author himself.

For the square plates B = L, and the corresponding thicknesses of plates are as follows :—

L =	2,	2½,	3,	3½,	3,	4½,	5,	5½,	6;
t =	.069,	.087,	.104,	.122,	.139,	.156,	.174,	.191,	.208;
Nearest corresponding gauge..... =	16,	14,	12,	11,	9,	8,	7,	6,	5.

The cost of buckled plates, compared with corrugated sheets, may be obtained thus :

Let the gauge be assumed to be 12 deg. to 14 deg.; therefore, the weights per 100 square feet will be for 14 gauge =

$$\left(3.12 + \frac{3.12}{70}\right) 100 = 316.8 \text{ pounds} = .14 \text{ tons;}$$

12 gauge=

$$\left(4.38 + \frac{4.38}{70}\right) 100 = 444.3 \text{ pounds} = .2 \text{ tons.}$$

The cost per ton is £13 in England, plus £7 for freight and carriage to 100 miles from the coast, equal, say, Rs. 200; therefore, the cost of buckled plates would be from Rs. 28 to Rs. 40 per 100 square feet, or about one-fourth less than that of corrugated iron.

The relative cost of the three sorts of covering for platforms of road bridges may be summarized as follows:—Timber planks, Rs. 50 to Rs. 80 per 100 square feet; corrugated iron sheets, Rs. 40 to Rs. 50 per 100 square feet; iron buckled plates, Rs. 30 to Rs. 40 per 100 square feet, to each of which rates must be added the expense of fixing the material, such as spikes and carpenters' labor for the planking; rivets, bolts, and screws, with smiths' labor, for the iron.

The following table and information is extracted from a circular, by Mr. Mallet, "On Buckled Plates"

Table of Strength, Weight, and Cost.

Thickness of Plates.		Weight per square yard of buckled plates.	Weight of an equal surface of corrugated sheet of corresponding thickness.	Safe passive load uniformly diffused, per square yard, for 3-feet square plates.	Safe impulsive load uniformly diffused per square yard, for 3-feet square plates.	Cost per superficial yard of buckled plate at £13 per ton, in England.	Nearest number of square yards in one ton.	Notes, etc.
in.	B. W. G.	lbs.	lbs.	tons.	tons.	s. d.		
.048	18	17.3	20.7	0.27	0.20	2 2	129	Applicable to roofing and flooring.
.066	16	23.6	28.3	0.43	0.32	2 10	95	
.107	12	28.7	46.4	0.64	0.48	4 7	57	
$\frac{1}{8}$	Nearly 11	45.0	54.0	1.0	0.75	5 3	49	For lighter class of bridge and other floors.
$\frac{3}{16}$	Nearly 7	67.5	81.0	2.5	1.7	7 11	33	
$\frac{1}{4}$	Nearly 4	90.0	108.8	4.5	3.0	10 6	24	For heavier floors of railway and other bridges and viaducts.
$\frac{5}{16}$	Nearly 1	112.5	135.0	6.2	4.7	13 2	20	
$\frac{3}{8}$	......	135.0	162.0	9.0	6.8	15 8	16	Not as yet been found necessary in any structure.

"The size of buckled plates formed of one single rolled plate is only limited by the breadth to which sheet or plate iron can be rolled at market prices.

"The sizes that have been found most advantageous for the majority of purposes are plates of 3 feet and 4 feet square, or of those widths by the full length of the plate.

"Buckled plates may be united to each other, or to the frame of the structure they cover, by either lap or butt joints, and either by screw bolts, rivets, or wood screws to timber, and the joints made absolutely water-tight, when required, by riveting and chinking up, or by interposed strips of tape or of felt saturated in oil cement, or in tar or pitch ; or by strips of vulcanized india-rubber; or a thin layer of oil-putty.

"Economy is always consulted by supporting each plate all round. One pair of opposite fillets, resting on the girders or joists, and the other pair supported by an angle iron above, thus forming a lap plate.

"Three-feet square buckled plates are made of all the thicknesses of the above table, and 4 feet square plates of all the thicknesses except the first two, as also any intermediate thicknesses at ordinary rates; others at extra rates. All buckled plates are charged by weight. The maker's price includes royalty.

"Prices are regulated by the 'declared rates' of the Staffordshire iron market."

THE MANUFACTURE OF PIG IRON.

BLAST FURNACE IMPROVEMENT—TREATMENT OF ORES.

Utilization of Waste Gases.—Mr. Chas. Cochrane's paper on this subject, before the Mechanical Engineers' Association, states that with the increased capacity of the present large blast furnaces in the Cleveland district, the waste gas is so far impoverished, both in quantity and quality, that, in order to maintain a uniform supply of gas for the steam boilers and hot-blast stoves, it is of importance to utilize the whole of the gas given off from the furnace, by preventing the loss of gas hitherto occurring at the times of lowering the closing cone or bell for charging the materials at the top of the furnace. This loss amounts to fully 6 per cent. of the total quantity of gas evolved from the furnace; and the escape of the gas at the furnace mouth occasions an interruption in the supply for heating purposes, and a liability to explosion on restoring the supply at the boilers and stoves.

These objections have been obviated by the writer by a plan of doubly closing the furnace top, the ordinary closing bell and hopper being completely closed in by the addition of outer cover, containing flap doors, through which the charging materials are filled into the hopper. These doors are closed at the time of lowering the bell for dropping the charge into the furnace, so that the only escape of gas that can take place is a quantity equal to the capacity of the hopper at each time of lowering the bell, which is insignificant in amount. The plan has been in successful operation for 9 months at the Ormesby Iron Works, Middlesborough. The saving of fuel in the ovens and boilers by having a continuous flow of gas, Mr. Cochrane estimated as about 9 tons a week per furnace, which, in the year round, represented a total saving of £150 to £160. The cost of the apparatus was £200.

Increased Size of Furnaces.—The second portion of Mr. Cochrane's paper had reference to the increased capacity of a furnace lately erected by him at the same works. The original furnace was 35 feet high and 16 feet diameter in the boshes, of a total capacity of about 7,000 cubic feet; it worked to a yield of rather over 30 cwt. of coke per ton of iron produced. The newly-erected furnace is 76 feet high and 23 feet diameter in the boshes, and of a total capacity of 20,624 cubic feet. It works to a yield of about 26 cwt. of coke per ton of iron produced, thus showing a saving of between 4 cwt. and 5 cwt. of coke per ton of iron. The Cleveland ironstone produces about 40 per cent. of iron. The author gave some interesting and detailed calculations, showing that the theoretical saving to be obtained by increasing the capacity of a furnace and thus making the materials in the upper portion act as a regenerator to take up the caloric from the incandescent materials below, was fully borne out in practical working. Following the line of these calculations, he estimated that a furnace, with 60,000 cubic feet of capacity and 113 feet high, should reduce the consumption of fuel to something like $7\frac{1}{2}$ cwt. per ton of iron produced. The extreme theoretical limit of economy, when the escaping gas would be reduced to the temperature of the external atmosphere, would be reached by increasing the capacity of the furnace to about three times that of the present large furnaces in the Cleveland districts.

In the discussion of the paper it appeared that one of the Ferry Hill Furnaces, Durham, was working with 16 cwt. of coke per ton. This was partly due to the height, 105 feet (25 to 26 feet boshes), and partly to the excellent hot blast stove used; the ore yield 57 per cent. against 40 per cent. in the Cleveland district. As to high furnaces, Professor Tunner states in a report on the Paris Exposition, that the results can only be considered important locally; such hard coke and such coarse aggregates of ironstones as are worked in the Cleveland district are not to be found again soon, nor everywhere. Whether or not the American anthracite coal will sustain such a burden, has not been determined; many authorities think it will. It is of the utmost importance to the Bessemer manufacture, at least, that the experiment be tried.

THE HOT BLAST.—An acknowledged progress has been made, says Professor Tunner, and is still becoming extended in application, in the heating of the blast to the highest possible degree. Even the coke-consuming furnaces, which are supplied with a cast-iron blast-heating apparatus, blow with air heated to 300° or 360° C.; but the blast-heating apparatus constructed upon the principle of Siemens' regenerator, of which there is also one in use at Friedrich Wilhelmshütte, near Siegburg in Westphalia, affords a still higher temperature, and would be more generally employed if its maintenance had not been found, so far, subject to so many interruptions and repairs, arising mainly from the interior lodgments of dust upon the brick heaters. With the high temperature of the blast is not only connected an enlargement of the furnace at the bottom, but at the same time a narrowing of the furnace mouth, and also with the complete disappearance of the boshes, whence has been attained the further advantage of a regular descent of the charge in work. The English and Scotch furnaces are distinguished in that way before all others.

GORMANS' GAS FURNACE.—Experiments in progress at the Gartsherrie Works are thus described: The furnace has two side channels or pockets extending vertically from the level of the tuyeres up to the charging platform, and forming special shafts or compartments for charging the coal into, while the ore, either all by itself, or mixed with an additional charge of coal, is brought into the blast furnace in the usual way; the furnace proper being open at the top. It is the intention to keep the coal separate from the ironstone until the former has been converted into coke, and the latter has arrived close above the tuyeres. At that place the side pockets which contain the charge of fuel open into the main stack of the furnace, and there the mixture between coke and ore takes place. The coal chambers are closed at the top, and the gas from the coal can be utilized as fuel or led into the main stack of the furnace for affecting the reduction of ore. In this manner it is expected that the ironstone will be reduced by the action of the ascending current of gas alone, and arrive at the openings of the side pockets in the state of spongy iron, or reduced metallic iron, which requires nothing but carburization for melting and running down into the hearth. The short space over the tuyeres should then act as a cupola for melting the spongy iron by means of the coke brought down into that space from the side pockets of the furnace.

"Engineering" says of this scheme:—The problem of separating the solid coal from the charge, and of reducing the ironstone by the action of gases alone, has never been brought to a satisfactory solution, however often and carefully experimented with. In the blast furnace itself the ore is in direct contact with solid carbon. In the higher zones of the furnace, where reduction takes place, an atmosphere of carbonic acid and of oxide of carbon exists at a temperature scarcely exceeding red heat, but the presence of coal and of oxygen from the iron ore seem to keep that atmosphere in a state of continuous charge between the higher and lower oxide of carbon. All particles of carbonic acid when in contact with coal become reduced to carbonic oxide, and the carbonic oxide in contact with the ore become carbonic acid again. This state of mobility or virtual motion of atoms seems to be requisite for the work of reduction, and it appears that an atmosphere of carbonic oxide alone is not capable of effecting the reduction of ironstone at that low temperature. It is clear, indeed, that the temperature maintained in the zone lowreduction is due to the presence of the solid carbon, since the process of converting carbonic acid into carbonic oxide by bringing it into combination with another atom of carbon is a cooling process absorbing fully one-third of the total heat which that carbon would evolve when completely burned in the open air. If we attempt, therefore, to effect the reduction of iron ores by a stream of carbonic oxide gas alone, we lose this cooling agency, we effect the combustion of the carbonic oxide gas at the expenses of the oxygen from the ore, and we thereby raise the temperature of the zone. The ore under these circumstances will become heated more and more until it will commence to melt without reduction. The furnace if kept hot enough at the tuyeres will then produce nothing but liquid oxides, silicates, etc., in the form of slag, which is simply the ore melted but not reduced. To obtain such a result, however, a great supply of heat from an exterior source is necessary, since there are zones below that zone of reduction just referred to, which require heat in order to keep the molten ironstone liquid at the time when it no longer gives off oxygen to the gas in contact with it.

In a common blast furnace where no such special source of heat is available, the probable result of a separation of the coal from the ore, would be to set the whole furnace fast in a few minutes. If, on the other hand, a regenerative gas furnace, or an air-furnace fired externally, is employed for that purpose, and connected with a stack or hopper for reducing the ore by ascending gas, a continuous and very profuse supply of liquid slag can be relied on, as the result of this mode of reducing iron ores by an atmosphere or current of carbonic oxide gas.

Carbonizing Ores.—A considerable economy in the reduction of iron ores is obtained at the Almond Ironworks, in England, by previously carbonizing or coking the ores, instead of merely calcining them. The process—Aitkens'—is largely illustrated in the "Practical Mechanics' Journal" of October last. It is stated that the carbon in the ores is retained, to serve for fuel in their reduction. Almost any apparatus suitable for coking coal may be employed.

Purification of Ores.—On this subject "Engineering" says: The rationale of the process of washing iron ores after calcination is the following:—An iron ore contaminated with pyrites, when submitted to calcination, under the free access and influence of the air, takes up a certain quantity of oxygen, and by that process the pyrites and other similar combinations of sulphur and iron become converted into sulphates of iron, which are soluble in water. If then the ore is washed with a large quantity of water and for a considerable length of time, all those soluble salts, and with them the component sulphur, will be removed. The purification from sulphur is most effectively attained by washing at the Kladno Ironworks, in Bohemia, where forge iron for puddling is the staple article, and at the Ironworks of Maria Zell, in Styria, producing foundry and Bessemer pig iron.

A new method of purifying iron ores now under experiment was patented by Mr. Thomas Rowan, of Glasgow, and consists in calcination and subsequent washing, only the calcination in this instance is not a mere oxidizing process as now practised, but the ore is mixed with chorides, such as common salt or chloride of manganese, and calcined in contact with these substances, the effect being to convert many of the substances contained in the ore into chlorides. The idea of removing phosphorus from iron by the action of chlorine was originated by Dr. Crace Calvert, of Manchester, more than twenty years ago, but it appears that Dr. Calvert expected a gaseous combination of phosphorus and chlorine to be formed and passed off as a vapour either from the blast furnace or calcining kiln. Mr. Rowan's researches seem to show that none of the volatile combinations of chlorine and phosphorus are formed during such a calcination, but that a combination is formed which is soluble in water, and can be extracted from the ore by washing after the calcination is completed. The effect of washing the ore after this chloridizing calcination is the removal of the sulphate of soda and of the clorides of phosphorus formed in that process.

It has been proposed, at one of the great ironworks in the Cleveland district, to effect this calcination by charging the ironstone mixed with salt into the calcining kilns now in use, but this is not a suitable mode of working on a large scale. The time for calcination, and particularly that for washing, should be ample, and much greater than can be allowed in the calcining kiln. The calcination should be carried on close to the mines in very large heaps covered at the top and connected at the bottom with flues which lead into a chimney. The salt mixed with the ore, or, still better, dissolved in water and sent into the calcining heap in the form of small jets or streams of brine, would act upon the mass for any desirable length of time. The whole calcining heap should, after being burnt out, be immersed with water, or be percolated by a large stream or body of water for several weeks. After this the ore may be sent to the smelting works, and the calcining kilns there will play the part of evaporators only. They will dry the ore and heat it to some extent previous to its being charged into the blast furnace.

SETTING OUT RAILWAY CURVES.

AN EASY CURVE FOR CONNECTING RAILWAY TANGENTS, WITH TABLES ADAPTED TO SETTING-OUT BY THEODOLITE.

By W. Airy, from "The Engineer."

It will, no doubt, be admitted by all who have had experience in the permanent setting-out of railways, that there is no method so rapid or accurate of setting-out curves as by theodolite. For preliminary work, indeed, it is possible to use other methods—the off-set method, for instance—with great success; but when a railway is formed, and the question is one of laying the rails to true curve, the theodolite method is the only reliable plan in practice. When, therefore, the writer of the present paper took the subject in hand, he made it a first consideration that no curve should be adopted which had not the property of being readily set out by theodolite; and the character of the curve and the form of the tables have all been suited to the above condition.

With regard to the necessity for such a curve, the writer takes that for granted. It is notorious that sharp curves are systematically "eased off" at the springing, in order to lessen the lateral shock to a train coming upon them off a piece of straight, but this very remedy may easily prove harmful, except the "easing off" is carried a long way up the curve, for it is clear that a curve cannot be flattened at one point without being rendered sharper at some other point; and if, as mostly happens, the curve is flattened at the springing without a careful adjustment of the curve for a long distance up, then a dangerous kink is left in the curve; and the writer has seen engines run off the line for this very reason. Various attempts have been made to ease off curves on a system; the curve of sines and the curve of adjustment have both been applied to the purpose; but neither of these curves is adapted to setting-out by theodolite, and the inconvenience of setting-out curves with poles on a railway nearly finished—and it is at that time that it has to be done—when the work is going on, and the way is much blocked with materials of all sorts, is almost intolerable, and renders any method of this kind quite impracticable.

The curve which is adopted in the present paper, together with the tables, was communicated to the writer by the Astronomer Royal; for the application of the curve nothing is assumed beyond the ordinary data, viz., two straight lines and the angle they include; the appended tables will then give all the elements required for laying down the curve on the ground, and for computing its length, etc., as may be necessary.

The curve is the cubical parabola whose equation is

$$y = \frac{x^3}{a^2}.$$

The chief advantage of this curve is that it hugs the tangent very closely for a long distance after leaving it, and thus the change of curvature is at first very gradual—which is the object in view. It has also the advantage of being the simplest curve of its class, and, by reason of the high powers involved in the expansions which occur when dealing with the properties of the curve, very close approximations are arrived at in very few terms of the series.

The denominator a^2, in the equation above given, as an arbitrary constant; and its value assumed for the formation of the present tables, $a^2 = 400$, has been chosen from the following considerations. Among the properties of the curve, it will be found that the radius of curvature decreases from infinity at the commencement of the curve, till it attains a minimum value at a point for which,

$$x = \frac{a}{\sqrt[4]{45}}.$$

Now, it is assumed that in setting-out railway curves, the ordinary unit of measurement will be the chain, and that, in general, the minimum radius of curvature allowed will be 10 or 11 chains; these, then, have been selected as conditions proper for determining the form of the curve, and the value of a^2, which has been adopted, will be found to produce a minimum radius of curvature = 11.3. It must, however, be observed that the foregoing assumptions merely fix the general shape of the curve, and do not in any way restrict the use of the curve to the precise conditions which were assumed in order to determine a suitable value for the constant; it will be at the option of the engineer to fix the minimum radius of curvature which he will admit, and the tables can then be used at once to set out the curve, so as to have that minimum radius of curvature, with this provision, that if the minimum radius of curvature which he adopts be other than 11.3 chains, he must work with a different length than the chain as unit. The method of fixing the unit and applying the tables will be seen in the examples below.

The tables are adapted to the method ordinarily pursued in setting-out circular curves; the successive unit lengths are chained along the curve, and the angles set off from the tangent by means of the theodolite. In ranging the curve, since the minimum radius of curvature is reached at a certain definite distance, in terms of the unit, from the tangent point, it may happen that this distance is less than half the length of the curve; in this case the curve is supposed continued with a circular curve of the said minimum radius until the half curve is completed, and the other half of the curve is ranged in the same manner from the other tangent point. There is no calculation involved in the above arrangement, but the necessary angles are taken out of the tables continuously and without interruption.

It may be well to describe the process to be followed in a given case. The first thing is to determine what shall be the sharpest curvature allowed, as this will fix the unit of measurement; the next thing will be with the known angular change of direction (this will be the same as the exterior angle between the tangents), to take out of Table I. the distance of the ends of the curve from the intersection of the tangents, in units of the length already determined; and thirdly, the theodolite must be planted at one of these points, and the half-curve ranged in successive unit lengths by the angles given in Table II.; the same must be done for the other point, and the curve is ranged.

Thus, for example, let the angular change of direction be 50 deg. and let it be determined to fix 15 chains as the minimum radius of curvature. From Table I. it appears that from an angle of 50 deg. the length of the semi-curve is 8.052. Also from Table II., it appears that at a distance along the curve of 8.0, the radius of curvature is 11.4. If, therefore, it be intended that this minimum radius of curvature shall represent 15 chains, the unit of length must be taken at $\frac{15}{11.4}=1.31$ chains; in other words, the unit must be a chain of 131 links.

Referring back to Table I., it appears that for angle 50 deg., the distance of the theodolite station from the intersection of the tangents is 8.456, or, using the proper unit, is $8.456 \times 1.31 = 11.08$ chains; and if this distance be measured along both tangents it will fix the two ends of the curve.

The theodolite may now be planted at one of these points, and the half curve ranged by means of the angles given in Table II., using throughout a length of 131 links as the unit. When half the curve is ranged, the theodolite must be shifted to the other end of the curve for ranging the other half.

In the above example it has been necessary to make use of a unit adapted to the conditions; but should the conditions be altered, so that the minimum radius of curvature, as found in the tables, and due to the angular change of direction, be not less than 15 chains, then the ordinary chain of 100 links can be used as unit. Thus, let the angular change of direction be 15 deg., then the tabular semi-length of the curve is 4.197, and the tabular radius of curvature due to this semi-length is nearly 16; consequently, the chain of 100 links may be assumed as the unit without fear of transgressing the fixed minimum radius of curvature, 15 chains.

With the foregoing explanation we may proceed at once to the tables:

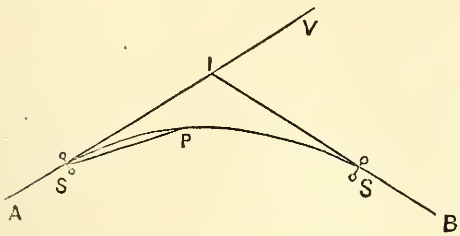
Let A I, B I, be the two tangent lines which are to be united by the curve, so that V I S, the angular change of direction, is a known angle; then, for the complete setting-out of the curve, we require to know the following elements:

1. The equal distances I T, I S, which define the theodolite stations, T and S.

2. The length of the curve.

3. The theodolite angle P T I, for successive points defined by the meas-

ure of successive unit lengths on the curve.



4. The radius of curvature for several points along the curve.

To supply these elements the two following tables have been computed :

TABLE I.—*Argument: The angular change of direction; giving the distance of theodolite station from intersection of tangents, and length of semi-curve.*

Angular change of direction.	Distance of theodolite station from intersection of tangents.	Length of semi-curve	Angular change of direction.	Distance of theodolite station from intersection of tangents.	Length of semi-curve.

PILES placed in the Rhine by the Romans, nearly 2,000 years ago, have been found to be entirely sound when removed within the present century.

CHIMNEYS.

The chimney of the West Cumberland Hæmatite Iron Works is deemed by Professor Rankine worthy of an extended paper before the Institute of Civil Engineers in Scotland, not because it is new or extraordinary in design, but because it is a successful example of the application of correct principles and good workmanship. We extract the following particulars :

	Feet.
Height above the ground line..........	250
Depth of foundation below the ground line (including a layer of concrete 3 ft. deep)	17

	Ft.	in.
Inside diameter at top of cone........	13	0
" " at 2 ft. above bottom of cone..............	21	10
" " of basement..........	18	10
" " of archways for flues..	7	6
Outside diameter at top of cone	15	3
" " at 2 ft. above bottom of cone.............	25	7

Outside dimensions of square basement.................. 30 ft. × 30 ft.

	Ft. in.		Ft. in.
Outside dimensions of foundation course......................	31 6	×	21 6
Outside dimensions of concrete foundation..................	34 6	×	34 6

The change from the square to the octagonal shape in the basement is made gradually by stepping the brickwork at the corners. A straight batter was used in preference to the theoretically correct curved batter, because the former could be tested by the eye.

The duty of the chimney is to carry off the gaseous products from 4 blast furnaces and various stoves and boilers—say from $10\frac{1}{4}$ tons of fuel per hour.

It had previously been ascertained, that in order that a round chimney in this windy region may be sufficiently stable, its weight should be such that a pressure of wind of about 55 lb. per square foot of a plane surface directly facing the wind, or $27\frac{1}{2}$ lb. per square foot of the plane projection of a cylindrical surface—that is to say, a pressure equivalent to the weight of a layer of brickwork 3 in. deep, and of an area equal to the vertical section of a round chimney—shall not cause the resultant pressure of any bed-joint to deviate from the axis of the chimney by more than one-quarter of the outside diameter at that joint. By calculating according to that principle the thicknesses of brickwork in the cone were determined to be as follows :

Uppermost	80 ft.	of height..	$1\frac{1}{2}$ brick.
Next	80 ft.	" ..	2 bricks.
"	88 ft.	" ..	$2\frac{1}{2}$ "

Lowest 2 ft., increasing by steps from $2\frac{1}{2}$ to 4 bricks, in order to spread the pressure on the basement. The bed-joint of least stability is 2 ft. above the ground line. The thickness of the arching in the openings for flues is three bricks. The following are the intensities of the mean pressures due to the load on different bed-joints :

	Tons on the Square foot.
At 2 ft. above the ground line..........	8
In basement at the springing of the arches	3
On the upper surface of the concrete...	2
On the ground below.................	1.6

The thickness of brickwork already stated, include the fire-brick lining, whose thicknesses are as follows:—In the uppermost 160 ft. of the cone, half brick; in the lower part of the cone, the basement, and the flue archways, one brick. The fire-brick lining is bonded with the common brickwork in the ordinary way—the fire-bricks are laid in the fire-clay and the common bricks in mortar. The reasons for adopting this mode of construction in preference to an internal fire-brick chimney are, 1st, the fire-bricks contribute to the stability of the chimney; 2d, unless the internal chimney is carried up to the top of the outer cone, there is a risk of damage through the explosion of inflammable gaseous mixtures in the space between; and, 3d, under the same circumstances there is a risk of the cracking of the outer cone at and near the upper end of the inner cone through unequal heating at that place.

Vertical cracks in a chimney are the more dangerous the higher the level at which they occur, because the safety of the higher part of a chimney depends more on cohesion and less on weight than that of the lower part. When such cracks take place near the ground, they are of little or no consequence.

The basement is paved inside with 6 in. of fire-brick, resting on 6 in. of common brick, which rests on the concrete.

The ordinary brickwork is built in English bond; in the basement there is one course of headers to every two courses of stretchers; on the cone, one course of headers to every three courses of stretchers. Strips of No. 15 hoop iron, tarred and sanded, are laid in the bed-joints of the common brickwork cone at intervals of 4 ft. in height, with their ends turned down into the side joints. In the concrete foundation, the basement, and a small part of the cone, the mortar was made of hydraulic lime; the mortar for the rest was made of a pure lime rendered artificially hydraulic by a mixture of iron scale in the following proportions :

Lime........................	2 measures.
Scale........................	1 "
Sand........................	5 "

The principal constituents of the iron scale are probably silica and protoxide of iron, but its action upon lime, and the nature of the artificial cement which it forms, have not hitherto been investigated by chemists.

On the top of the chimney is a pitch-coated, cast-iron curb, 1 in. thick, coming down 3 in. on the outside and inside. The lightning conductor is a copper wire rope, about $\frac{3}{4}$ in. diameter. It terminates in a covered drain, in which there is always a sufficient run of water.

In the construction of the internal scaffolding care was taken that the horizontal beams should be supported wholly by the brickwork, and not by the upright posts; for great danger has been known to arise from the brickwork coming to bear upon the ends of the needles, and through them on the posts, owing to the settlement of the lower part of the chimney.

In order that the concrete foundation might have time to harden before being subjected to a heavy load, it was made by the Iron Company themselves before the contract for the chimney was let; for it is known that intense pressure tends to retard the hardening of concrete. The progress of the building was restricted by the specification to a rate not exceeding 6 ft. of vertical height per day.

The work was executed by Messrs. Wm. Wilson & Son, Glasgow. The estimated cost was £1,672; the actual cost, including designing and superintendence, £1,560; being at the rate of almost exactly fourpence per cubic foot of the whole space occupied by the building, which is 94,000 cubic feet nearly.

According to the latest account, the temperature inside the chimney, when doing about three-fourths of its full duty, is 490° Fah.; and the pressure of the draught is $1\frac{7}{8}$ in. of water, which agrees to a very small fraction with the pressure as deduced theoretically from the temperature and the height of the chimney.

The dimensions and stability of the chimney which has just been described are nearly the same with those of the second highest chimney at St. Rollox Chemical Works, built about ten years previously, except that in the older chimney the joint of least stability is 100 ft. above the ground.

In the great St. Rollox chimney, $445\frac{1}{2}$ ft. high from foundation to top, the greatest pressure of wind which can safely be borne is almost exactly the same. The bed-joint of least stability is 210 ft. above the ground. In the great Port-Dundas chimney, 468 ft. high from foundation to top, the bed-joint of least stability is 200 ft. above the ground; and the greatest safe pressure of wind is 67 lb. per square foot of a plane surface, or $33\frac{1}{2}$ lb. per square foot of plane projection of a cylindrical surface, so that there it may be considered that there is an excess of stability.

One of the richest and most ornamental of modern chimneys is connected with the new India mill, Dorwen, Lancashire. The total height of the chimney shaft from the bottom of the foundations to the top of the iron cresting is $310\frac{1}{2}$ ft., and from the ground line 300 ft. The base is of solid ashlar, 29 ft. square at ground line, and 42 ft. high. The stone cornice to the base is 35 ft. long on each of the four sides. The shaft itself is built with red, white, and black bricks, with sand gritstone dressings, and is 24 ft. square, and built perfectly plumb. The walls are 3 ft. thick at top of stone base, reduced by "offsets" on the inside to 23 in. at the commencement of main cornice, which is 255 ft. above the ground. Many of the stones used in this cornice weighed as much as 5 tons each, and were hoisted by steam power. The balusters surmounting this feature are of cast-iron, as also are portions of the 4 vases at the corners. The crown mould of the cornice at the top of the shaft projects more than three times as far over the wall as it rests on it, and was kept in its place by iron cramps until the cast-iron cresting was fixed upon it. This cresting contains about 20 tons of metal, and is composed of more than 300 castings. There is no bolting nor any particle of wrought-iron in this portion of the work, the parts being kept together by slots and lugs. The whole weight of this cresting stands upon the brickwork, and keeps the upper stone cornice firmly in position. There is an interior and totally independent shaft, 180 ft. high, to prevent the great heat from the boiler furnaces subjecting the wall of the outer and main shaft to unequal expansion and contraction.

MODERN ARCHITECTURE.

THE OFFICE OF ART IN ENGINEERING.

It may be stated, as a general rule, that whatever in construction—in engineering construction even—is true and suitable and proportioned to strains and service, is also beautiful; or if this statement is too broad, it will not be denied that those structures in which material is utilized and power is applied to the best advantage, are the most beautiful and pleasing. This is as true of a connecting rod as of a cathedral. The art element should therefore be considered in engineering, on professional grounds as well as in the general interests of civilization and refinement. In architectural construction, and in all great or conspicuous engineering works, the want of farther ornamentation and balance of parts may often appear after the strains and functions are all provided for, but it will nevertheless be found, when "artistic effect" is *stuck on* by an afterthought, that both truth and taste have been violated. The artistic element must be associated with the design from the beginning. The following extracts from an article entitled "Modern Architecture—the Philosophy of Failure and the Secret of Success," are from "The Building News":

It will be admitted by intelligent observers of all schools that modern architecture regarded from an art point of view is not a success. We have huge edifices, triumphs of engineering skill, imposing piles of building resplendent with tropies of the stone-carver's craft, and magnificent erections of iron and glass, marvellous as specimens of metalwork, and gorgeous in their effect. Nevertheless we have no distinctive and satisfactory style, no precise principle of construction, no characteristic method of ornamentation, and no practical power of realizing that idea of *beauty* which hovers in thought before the mind of every intelligent designer.

It may seem but the repetition of a hackneyed truism to assert that the *true* and the *beautiful* are inseparable. Yet if we are not greatly deceived it is because in modern architecture these two qualities are regarded and treated as separable that the practice of art is a failure. As a matter of fact the attainment of beauty is proposed as an object altogether apart from the consideration of truth.

The architect who designs his building on a purely utilitarian principle, trusting to his ingenuity to make it beautiful by a subsequent process of ornamentation, is practising an æsthetic fraud. His edifice is not beautiful in itself, he is conscious of its defect; hence he labors to give it a meretricious aspect by means of ornament. Is it wonderful if he fails? Again, the designer who distorts the constructional parts of his work with the aim to realize something of beauty is no less untruthful, inasmuch as the ornamental feature, the façade or the tower he contrives to produce, are not necessary—they form no integral part of the utile edifice. The public eye quickly detects the artifice.

In illustration of these supposed classes of work, and in proof that they are not imaginative, it is only necessary to instance the numberless hotels, stations, warehouses, and public buildings scattered throughout the country which in themselves are ugly, but to the perverted vision of a vitiated taste are made tolerable by an incrustation of cornices, carved friezes, statuettes, intricate metalwork and elaborate ornament. These are examples of buildings erected without a thought of beauty and beautified afterwards. The class of works which are untruthful in their form, and ape beauty rather than possess it, may be illustrated by the 12 or 14-roomed houses fashioned like castles, the insurance offices and banks built to resemble edifices of great civic importance. The cloistered bath and wash houses, the club houses and reading rooms, like Greek or Roman temples, the divans like ducal palaces, and the parish churches in town and country constructed as cathedrals—all these things are *deceptive,* and it is because they transgress the principle of truth and regard the attainment of beauty as an object to be gained apart from truth, and even in violation of its immutable and universal laws, that they are failures.

Among the examples of works designed in neglect of the principle of truth, Silesbury Cathedral is mentioned; its chief defect is weakness. The violation of engineering truth at once impairs the artistic effect.

It is a task of great difficulty to define the precise conditions of architectural truth. On the first blush of the matter it is self-evident that there must be purity of intention in the design. If a man sets out with the purpose of building a barn, it must not be a Swiss villa or a Chinese joss-house that he plans—it must be a barn pure and simple. The practical error takes its rise in the false notion that certain objects are more respectable and pleasing than others, and, falling into the vicious practice of flattery, the architect deems it more complimentary to the feelings of his client or considerate to public taste to make his barn look like something very charming, light, and graceful. Now, truth would forbid all such misrepresentation of fact, and would interdict all meretricious ornament. It would require a grandeur, and a style and degree of ornamentation, befitting the nature of the building and the purpose to which it was to be applied, but it would not allow the enrichment of a plain mass with a view to raise it to the pitch of beauty supposed to be possessed by a building of more elaborate figure. This was the principle on which the designers of the best and purest epochs in the history of art acted. The works which have been preserved for us from the thirteenth century are eminently *truthful* in their intention. They tell the story of their use without disguise or prevarication. They do not seek to appear more noble or higher in the scale of beauty than they are placed as respects the arrangement, configuration, and balance of the masses of which they are composed. The ornament is never excessive, it never belongs to a class of building more elevated or elaborate than that to which it is applied; it never suggests the idea that the designer aimed to make his work look *enriched* or beautified. Simplicity and truth are characteristics of a style which all accept as thoroughly honest and pre-eminently respectable.

The error into which the Gothic revivalists have fallen is that they have attempted to produce the *form* of mediæval work but neglected the *spirit*. Now it must be evident that much of the architecture which we admire in its place, amid the associations of the thirteenth century, would be anachronic, however skilfully reproduced in the nineteenth century. What we want is a revival of the old spirit of manly outspoken honesty and the love of truth which animated the old art-architects. Special developments of art are inseparably connected with conditions of time, place, and circumstance. We cannot live, and dress, or build as they did who lived in the thirteenth century, but we can subject ourselves to the same pure and simple influences of truth which swayed their minds.

MANAGEMENT OF SMALL TUBULAR BOILERS.

Under the head of management of portable engine boilers, a correspondent of "The Engineer" gives some useful information on this subject. The boilers referred to are of the locomotive type. The cylinders are usually at the fire-box end, and the exhaust pipe passes inside or outside the barrel to the blast nozzle. The feed-water enters the boiler in some cases through the tube plate of the barrel, but more generally through the underside of the barrel near its front end.

For washing out the boiler there are generally 7 mud holes, 1 at each corner round the bottom of the fire-box, and 1 at the bottom of the smoke-box tube plate; the number and position of these holes are very inadequate to the thorough cleansing of the boiler from the dirt and impurities which enter with the feed-water, and which, if not constantly and easily removed, soon fill it with incrustation; the parts that suffer most from this great enemy to all boilers are the water spaces and stays around the fire-box, and among the tubes in the neighborhood of the feed-pump, the greatest amount of incrustation being formed in the front water space of the fire-box where no mud holes exist. To remove the deposit from this space, the best plan is to cut a mud hole in the outer plate at a short distance below the tubes, and as near the middle of the plate as practicable; by this means the dirt which drops down from the tubes is easily removed. One or two additional mud holes arranged in a higher position round the fire-box shell, would also prove of great assistance in keeping the stays free from corrosion.

In the neighborhood of the feed-pump, and immediately opposite the orifice in the boiler, incrustation is rapidly formed among the tubes; so much so, that the spaces between them, and even the feed orifice itself, become sometimes completely choked with dirt. The consequence is, that the water delivered by the pump not having free admission to the boiler, causes shortness of water and constant breakage of the working gear. For cleaning this part of the boiler, a plan I have generally adopted with success is to fix a 2-inch gun-metal plug at the side of the smoke-box tube plate and clear of the tubes, directly in a line with the feed orifice; by occasionally removing this plug and introducing a rod, the incrustation which forms round the feed orifice is broken up and falls to the bottom of the barrel, whence it is removed through the existing mud hole. It is also well to fix a half-inch plug in the side of the feed-pump valve box, immediately opposite the delivery orifice in the side of the boiler. A rod introduced through this hole will always keep the delivery pipe free from corrosion. To still farther prevent the accumulation of dirt, it will be found a good plan to draw a few tubes periodically—say, half-a-dozen on the feed side; by this means the incrustation formed among them can be quickly and completely removed. A good boiler-maker will draw these tubes without damaging them, and they can then be put in again; but even if 1 or 2 of them fail and require renewing, the expense of the new tubes is soon saved by a decrease in the consumption of fuel consequent upon a clean barrel. I have generally found it to be further advisable at the end of 12 months, if the boiler has been pretty regularly worked during the time, to draw all the tubes, and by sending a boy through the manhole into the boiler, the water spaces and barrel can be thoroughly cleaned, and the tubes, which become coated with a hard scale, can be scraped, and renewed where damaged or burnt. At the same time all leaky stays round the fire-box should be drilled out and replaced by stays of S. C. iron.

The expense of these operations is fully compensated for by the increased efficiency and durability of the boiler.

The joints about a portable engine boiler next demand attention. These are a constant source of trouble and expense. In cases where the exhaust pipe passes through the boiler, the flange joints in connection with the cylinder eduction ports in the top plate of steam chest are continually failing, and the steam entering the leak causes a continual blast through the exhaust pipe, and a great loss of steam. In breaking and making these joints afresh, the screws which secure them, and which are tapped into the base of cylinders, break short off inside the boiler; the consequence is that the cylinders have to be lifted and the screws renewed, which is a very expensive and tedious job. A great improvement is to substitute studs for screws, with nuts inside the boiler. In some portables where the exhaust pipe passes along the top and outside the boiler, this leakage is avoided.

Failure often takes place in the joint or bedding of the cylinders on the boiler, the base or flange of the cylinders not being properly brought to a true bearing on the crown plate. This joint is well made with wire gauze, and red and white lead, but an equally good, if not better, joint is made with iron borings and Scotch cement.

Leakage is constantly taking place among the tubes, and among the bolts and studs connected with the boiler, viz.:—The fire-box bridge bolts, the cylinder and saddle bolts, and the studs securing the fire-bar bearers to the sides of box. Excessive leakage in the ends of the tubes is a sure sign of an accumulation of dirt behind the tube plate; this dirt being first removed, the tubes can be made tight by judicious caulking; continual caulking, however, is very injurious to the tubes and plate, and whenever this fails, the ferule should be withdrawn and replaced by one slightly larger in diameter. A good grummit for the heads of the fire-box bridge bolts is made of spun yarn, with a thin coating of Scotch cement; leakage in the saddle bolts is not easily remedied; being put in from the inside of boiler, great difficulty is experienced in reaching them. The fire-bar bearer studs are not made strong enough for the weight they have to carry, and when leaky are very troublesome; the best plan is to replace them by larger screws of S. C. iron.

It is almost unnecessary to add that the water-gauge cocks, the blow-out cock, and safety-valve fittings, require constant looking to, and should be always kept free from corrosion and in good working order.

It cannot be too often impressed upon engineers in charge of steam-boilers, that the great desiderata for their safe and economical working are :—careful engine-men, good and constant supply of pure water, entire freedom from dirt and corrosion, and tightness in every part; by a proper and systematic attention to these points a boiler can always be kept efficient and safe from accident, and will last for years.

Painting Zinc. — A difficulty is often experienced in causing oil colors to adhere to sheet zinc. Boettger recommends the employment of a mordant, so to speak, of the following composition :—One part of chloride of copper, 1 of nitrate of copper, and 1 of sal-ammoniac, are to be dissolved in 64 parts of water, to which solution is to be added 1 part of commercial hydrochloric acid. The sheets of zinc are to be brushed over with this liquid, which gives them a deep black color; in the course of from 12 to 24 hours they become dry, and to their now dirty gray surface a coat of any oil color will firmly adhere. Some sheets of zinc prepared in this way, and afterwards painted, have been found to entirely withstand all the atmospheric changes of winter and summer.

Cement for Steam and Gas Pipes.—The following directions are given for making cement impermeable by air and steam, which is said to be superior to any in use for steam and gas pipes :—Six parts of finely-powdered graphite, 3 parts of slaked lime, and 8 parts of sulphate, are mixed with 7 parts of boiled oil. The mass must be well kneaded until the mixture is perfect.

NEW THEORY OF PUDDLING.

THE AGENCY OF CARBONIC ACID GAS.

Mr. John F. Bennett, of Pittsburgh, who has taken a patent for the use of carbonic acid gas in the Bessemer converter —a process about to be tested in Sheffield, we understand—writes at length to the "Iron Age" (Dec. 3) on a kindred subject. After quoting Dr. Percy's theory of puddling, which has been the received theory of all writers from Kane in 1835 to Fairbairn in 1865, he objects to it in detail, and states his own views with at least considerable plausibility. The following are the points in the case :

The only air that enters the furnace passes up through the grate bars of the fireplace, and is wholly changed into carbonic acid gas. As there is not enough air to consume all the combustible matter, part of it passes off as distilled gases, and part of the carbonic acid gas is decomposed into carbonic oxide gas; in both cases not giving out their value, and so causing waste of fuel and loss of heat and time. The writer built a puddling furnace which is now in successful operation, into which is drawn, immediately beyond the fire bridge, a quantity of hot air equal to one-third of what passes through the grate bars. This scarcely suffices to burn all the combustible matters. In the Silesian gas puddling furnaces the supply of air is exactly proportioned to the combustible gases. So also in the Siemens' furnace. But if free oxygen did pass over with the unconsumed combustible gases, and would combine with carbonic acid sooner than with iron, how much rather would it prefer the gaseous carboniferous matters amongst which it is infused, to the partially liquid iron on the bed of the furnace, against the surface only of which it could impinge. Therefore, there is, practically, no free oxygen influencing the action in the puddling furnace.

With regard to the blue flames of carbonic oxide gas issuing from the surface of the molten metal, produced by the reaction between the carbon of the pig-iron and the oxygen of the oxidized compounds of pig-iron, as Dr. Percy states—these blue flames of carbonic oxide gas must have some other origin, inasmuch as the protoxide of iron in the puddling furnace cinder is increased at each operation, and not decreased, as would be the case if Dr. Percy were correct; also it is unknown in chemical reactions that the oxygen of the protoxide of iron can be removed by carbon. Nor will oxygen combine with carbon to form carbonic oxide gas so that it can be exhibited, for although carbon does undoubtedly unite with its equivalent oxygen to form carbonic oxide gas in the first instance, when they come together at the proper temperature, yet such is the affinity of carbonic oxide gas for oxygen, that at the moment of its formation, it combines with it and forms carbonic acid gas—or, in other words, if 1 atom of oxygen was present with 1 or more atoms of carbon at the proper temperature, carbonic acid gas would be produced and might be exhibited, but if 2 atoms of oxygen and 1 or more atoms of carbon were present, carbonic acid gas alone would be produced and exhibited; therefore, practically, oxygen burning with carbon would produce only carbonic acid gas, and not the well-known blue flames of carbonic oxide gas as exhibited in the puddling furnace of the iron works, or the black ash furnace of the alkali works. Therefore, says the author, the process of eliminating carbon from iron in the puddling furnace is not assisted by the oxygen of any part of the cinder, or of the oxidized compounds of iron added during the process.

Mr. Bennett's theory is as follows: On the bed of the puddling furnace we have molten pig-iron, consisting of iron, carbon, sulphur, phosphorus, silicon, manganese, aluminum, calcium, magnesium, etc., played over, surrounded, and permeated with hot carbonic acid gas. That portion of the atmosphere of carbonic acid gas that permeates the liquid pig-iron may be looked upon as liquid, thus allowing free play for chemical affinities to display themselves as readily as they do when different salts of hydrogen are dissolved in water and commixed. In the order of their affinity, the silicon and carbonic acid first combine, depositing carbon in the molten pig-iron, while the silicic acid is evolved as a gas in part and deposited in the liquid cinder in part. Co2x=Cx2 Si. O. While this operation is going on there is an increase of carbon in the molten pig-iron as shown by the experiments of Calvert and Johnson and M. Lan.

The carbonic acid next combines with the carbon forming carbonic oxide, which is evolved as a gas. Co 2 xC=2 Co. The carbonic acid next combines with the sulphur, depositing carbon and evolving sulphurous acid and sulphuric acid, which is in most part retained in the liquid cinder as sulphate. The carbonic acid next combines with the phosphorus, depositing carbon and evolving phosphorus and phosphoric acid, which is in most part retained in the liquid cinder as phosphate. The carbonic acid next combines with the manganese, depositing carbon and evolving manganous acid, which is in most part retained in the liquid cinder as protoxide. The minor impurities of magnesium, calcium, aluminum, etc., are removed in the same manner.

That this is substantially the order in which these impurities are removed may be shown in the action of the blast furnace, where, when these are the impurities of the iron ore smelted, if the manganese is deposited in the slag, so are the sulphur and phosphorus, while if the manganese remains in the pig-iron, so do also the sulphur and phosphorus. While these three last operations are going on, the carbon deposited is also acted upon by the carbonic acid and evolved as carbonic oxide gas.

While all these operations are going on, the iron is also acted upon by the carbonic acid, carbon deposited, and ferrous acid in part evolved as a gas and in part deposited in the liquid cinder as protoxide. While the action is taking place between the carbonic acid and the following substances, viz., silicon, carbon, sulphur, and phosphorus, both being hot, say 3,000° Fahrenheit, there is no diminution of temperature. When the action begins to take place between the carbonic acid and the iron, there is a deficiency of temperature manifest, and the iron begins to be pasty and capable of being agglutinated together, and so collected into balls, this deficiency of temperature being caused by the temperature of the carbonic acid being only 3,000° Fahrenheit, whereas pure iron requires a temperature of 5,000° Fahrenheit to become liquid, and in the action of the transfer of oxygen from one metal to another there is no heat made apparent; or, in other words, the heat lost by the taking away of the oxygen of the carbonic acid is at the same time restored by its combination with the iron.

NEW EXPLOSIVE AGENTS.

Compiled from the "Pall Mall Gazette."

NITRO-GLYCERINE.—Mr. Alfred Nobel, a Swedish engineer and chemist, was the first to attempt the application of nitro-glycerine as an explosive agent, although it had been known as a chemical curiosity since 1847. His original plan was to impregnate gunpowder with the liquid, thus adding very considerably to the destructive powers of the former. It is a peculiarity of nitro-glycerine that, although it explodes violently when submitted to a sudden and sharp concussion, it is flamed with difficulty by the simple application of heat or fire, and then burns very much like any inflammable, non-explosive liquid. About five years ago Mr. Nobel adopted the ingenious device of accomplishing the main explosion by a small preliminary detonation, by means of the ordinary mining fuze, with a small case containing gunpowder, or a metal cap containing detonating powder, attached to its extremity. Thus the destructive force of nitro-glycerine may be developed with tolerable certainty, no matter whether the liquid is more or less strongly confined.

The possibility of applying nitro-glycerine in its pure state as an efficient explosive agent, in mining and similar operations, having been thus demonstrated, Mr. Nobel proceeded to perfect the manufacture of the material, and to give illustrations in public of its extraordinary destructive powers, which have been estimated at 10 times as great as gunpowder.

The new "blasting oil" was first used in Sweden and Norway, where manufactories were established by Nobel, and subsequently in other countries; notwithstanding the difficulties and dangers to be encountered in the employment of a liquid of uncertain stability, possessed of poisonous properties, horribly dangerous to handle, and having the tendency to solidify at a temperature above the freezing point, when the danger attending its manipulation becomes greately increased. A succession of the most fearful disasters have occurred during the transport, manufacture, and manipulation of the substance, the first at Colon, and others in New York, California, Australia, and other parts of the world, also two destructive explosions last summer in Belgium and in Sweden (at Nobel's factory). The employment of nitro-glycerine has since been prohibited in the two last-named kingdoms, and the very name of the substance is now everywhere most properly regarded with a feeling of dread, which any modification in the properties of this destructive liquid will fail readily to dispel.

DYNAMITE.—These facts have led Mr. Nobel to contrive a safer modification of the liquid; the result has been the production of "dynamite," a buff-colored powder, somewhat oily or adhesive to the touch. This material is a somewhat crude nitro-glycerine preparation, and consists simply of a silicious earth (or any other inert powder), impregnated with a considerable quantity of nitro-glycerine. A solid, inert substance is thus made the vehicle for the application of the explosive liquid, and the disadvantages which specially attach to the fluid character of nitro-glycerine are set aside. But although nitro-glycerine in this form is safer to transport, and is applicable with more ease and certainty as a blasting agent than the liquid, its injurious influence upon the health of those employing it, and the possibility of its undergoing changes which may result in spontaneous explosion, are not overcome. Moreover, the physical character of dynamite renders it less convenient to handle than gunpowder and other solid explosives; and it is obviously less powerful than the undiluted liquid. Like nitro-glycerine in the pure state, dynamite will not explode upon simple application of a red-hot iron or flame, but if exposed to the effects of a detonation in immediate proximity to it, the violently destructive results obtained with the liquid are developed in proportion by the solid.

NYTRO-GLYCERINE AND GUN-COTTON.—Another preparation of this substance has lately been produced by Mr. Abel, Chemist to the War Department, and made the subject of some interesting experiments at Chatham and Woolwich. It is produced either in the form of hard granules, or of discs or pellets of compressed gun-cotton, containing about three-fourths their weight of nitro-glycerine. The nitro-glycerine is thus held absorbed within a porous, solid substance, which is itself endowed with strong explosive properties. All contact of the nitro-glycerine with the air, and with those handling this preparation, is prevented by a hard impervious coating with which the grains or discs are provided. This material would therefore appear to be decidedly safer and more convenient to handle, transport, and preserve, besides being more powerful as an explosive than dynamite. If lighted in open air it simply burns, without any explosive effect; but when confined it does not, like dynamite or the liquid nitro-glycerine, require a detonating fuse for the development of its explosive power, though its violent explosion, even in open air, may be brought about in that way, just as in the case of the other substances.

Improved Gun-Cotton.—Unfortunately for the interests of nitro-glycerine, a new and valuable addition to our knowledge of gun-cotton, recently made at Woolwich, renders it very doubtful whether the explosive liquid, in whatever form it may be presented, is likely to enter into successful competition with that material. It has been found that the explosive force of gun-cotton may, like that of nitro-glycerine, be developed by the exposure of the substance to the sudden concussion produced by a detonation; and that if exploded by that agency, the suddenness and consequent violence of its action greatly exceed that of its explosion by means of a highly heated body of flame. This is a most important discovery, and one which invests gun-cotton with totally new and valuable characteristics.

Some remarkable results have been already obtained with this new mode of exploding gun-cotton. Large blocks of granite and iron plates of some thickness have been shattered by exploding small charges of gun-cotton, which simply rested upon their upper surfaces. Long charges or trains of gun-cotton, simply placed upon the ground against stockades of great strength, and wholly unconfined, have been exploded by means of detonating fuses placed at the centre or at one end of the train, and produced uniformly destructive effects throughout their entire length, the results corresponding to those produced by eight or ten times the amount of gunpowder when applied under the most favorable conditions. Mining and quarrying operations with gun-cotton applied in the new manner, have furnished results quite equal to those obtained with nitro-glycerine, and have proved conclusively that if gun-cotton is exploded by detonation it is unnecessary to confine the charge in the blast-hole by the process of hard-tamping, as the explosion of the entire charge takes place too suddenly for its effects to be appreciably diminished by the line of escape presented by the blast-hole. Thus, the most dangerous of all operations connected with mining may be dispensed with when gun-cotton fired by the new system is employed.

It will readily be observed that this discovery, which we believe is due to Messrs. Abel and Brown, of the War Office Chemical Establishment, is likely to be attended with most important results. It has been said, and said justly, that if you want gun-cotton to exert itself you must coax it into the belief that it has a great deal to do. You must give it bonds to break and physical obstacles to overcome, with no outlet or possibility of escape. But now, gun-cotton will exert itself, and put forth more than what was believed to be its full strength, whether it sees any work to do or not. This discovery, therefore, can hardly fail to lead to the universal adoption of gun-cotton for mining purposes, as soon as its new properties become generally known.

In connection with possible military applications the discovery is invaluable. There can no longer be any doubt what agent should be employed for the breaching of stockades and the like; and the absence of all necessity for the use of strong confining envelopes will have an important bearing upon the employment of gun-cotton for torpedoes and all submarine explosive operations, besides greatly simplifying mining and breaching operations in the field. We have, in fact, discovered several new advantages to add to those which already had sufficed to recommend gun-cotton as an explosive agent in preference to all others.

Isaac Newton, Esq., late Chief Engineer in the Navy, Engineer of the Monitor during her first engagement, and an accomplished scholar in all that pertains to ships, steam, and naval affairs, is associated with Gen. McClellan in the completion of the Stevens battery.

WASTE OF WOOD.

STATISTICS—THE REMEDY—IRON AND CONCRETE STRUCTURES.

From the last report of the United States Department of Agriculture it appears that unless measures are taken immediately to replace by new plantations the supplies withdrawn by the destruction of our old forests, there will be an actual famine for wood in this country within the next 30 years. It is estimated that from 1850 to 1860 no less than 50,000,000 acres of new land were brought under cultivation, of which two-fifths were timber land. And in the decade ending 1870 there will be no less than 100,000,000 acres so reclaimed. In the single State of New York, from 1850 to 1860, there were reclaimed from the forest and brought into cultivation no less than 1,967,433 acres of land. All these acres will never again be devoted to timber growing, and still the destruction goes on.

The great consumption of wood is for building, fuel, and railway sleepers. The value of the farms of the United States in 1860 was $6,654,045,700, while the value of the lumber improvements was $3,322,522,000. All this has been cut from the soil, and most of it within 30 years. Little or nothing has been done to replace it. The sleepers used on the railroads of our country from 1850 to 1860 cost $23,063,957. More than 100,000,000 railway sleepers are now in use, and as these are almost entirely hard wood, and last but 2 to 5 years, it will be seen that the annual supply for this purpose is enormous, and increasing as fast as new railroads are built. In a single year there was used for repairs of railroads and railroad buildings and cars in the United States, no less than $38,000,000 worth of wood.

There are no less than 477,623 artisans in wood in this country. If we estimate the value of their production at the low price of $1,000 each per annum, we have the still greater aggregate of an industry of $500,000,000 per annum dependent solely on wood. It is a noteworthy fact that wood in all its branches of manufacture and use, pays more than one-half the entire internal revenue of the United States, and no less than 66 trades depend upon wood as bare material for their labor. The wood fuel used for locomotives in the United States reached the enormous figure of $56,000,000 in a single year.

Besides the scarcity and increased cost of wood for all these purposes, a more serious loss is likely to result to agriculture, from the greater severity of the climate, due to the loss of the forests. The irregularity and extremes of temperature we now endure, were not formerly known.

These are startling facts, and their importance cannot be too quickly or too seriously considered by governments, communities, engineers, farmers—all men. The people should rise in self-defence, as in case of foreign invasion. Without discussing at this time the proper work of Government in the matter, nor of farmers in replanting and sparing forests for their individual protection, we would urge engineers, builders, and all consumers of wood in great and permanent structures, to renew their efforts to cheapen the other and more plentiful materials of nature, and more especially to *avoid the use of perishable wood.* In the majority of cases the use of wood costs more in the long run than stone, brick, cement, iron. Decay outruns interest.

Wooden railway bridges do not pay anywhere, and wooden sleepers are not found to pay in many countries where this material is peculiarly scarce and perishable. Iron sleepers, with a small amount of wood in pockets, to give the necessary elasticity, are really permanent and safe, and would be economical to-day on lines of heavy traffic in our Eastern States. The wear and tear of rails and rolling stock directly due to the decay and the cutting and mashing of wooden sleepers, the cost of their renewal every five years, and the better support and increased bearing of the rail obtainable with iron, are all sound and weighty arguments in its favor. Because simple stone blocks were found too rigid, the idea of stone permanent way seems to be entirely discarded. But where stone is plentiful and easily wrought, the placing of wooden pockets in large blocks of it would cost little more than wooden sleepers, and be sufficiently elastic.

Excepting only wooden shipbuilding, the most unreasonable and not the least extensive use of wood is in the floors of great stone and brick city houses. Probably three-quarters of the very first class and most costly buildings erecting in our cities, have wooden floors. The first cost of iron is certainly a great temptation to avoid it; but higher rates of insurance and inevitable destruction by fire at some time, will eat up the saving. If wood and iron were of equal price, the permanence of the latter should warrant its adoption in all the better class of buildings. There is some reason and hope in legislation on this subject. When a man's wooden-floored warehouse is gutted by fire, the verdict is, "served him right." But when this conflagration lights the warehouses of his neighbors, they have a rightful and should have a legal claim against him. For farm buildings and country houses brick should be more generally adopted as an economical measure; the repeated painting and inevitable decay and reconstruction of wood cost more in the end Concrete is getting into larger use, especially abroad; it is cheap and permanent. This subject will be more fully referred to in another article.

What engineers and builders have to do is to *cheapen* brick, concrete, artificial stone, iron, and the modes of moulding them into houses and structures. The wood question is so positively alarming, that a great demand—a rush—is likely to be made in the new direction, and every improvement will be gladly and widely welcomed. We know of no business likely to be more remunerative than the production of a cheap mineral building material, on a large scale.

As to wood fuel, the grand consumption of locomotives and steamers is already much abridged. The charcoal furnace is a great destroyer of forests, and we look to the improvement in coal furnaces—high and large stacks, better hot blast, better fluxing, and the purification of ores and of irons in subsequent treatment—to lessen the necessity and the demand for charcoal-iron.

It is singularly fortunate that the material we want so much to preserve, is the material we ought so little to use. Wood in heavy and exposed structures, and especially when subjected to wear, is utterly perishable. It immediately begins to depreciate in strength and value, and its short life is but a series of paintings, patchings, splicings, and repairs. For this reason it is after a short service not only unreliable, but so yielding as to decrease the service and durability of surrounding parts. If this is not enough, the injury to agriculture by the destruction of forests, should be enough to warrant every public and private effort to preserve them. The cultivated taste of the times has found nothing more suitable for furniture and decoration than the natural woods, and whatever of this material can be spared from the hill sides can be advantageously employed for these and similar purposes.

In the West this subject is better understood than among us, and laws have already been passed in Iowa, Kansas, Missouri, and other States, looking to the growth of forests, such as the exemption of made and natural wood growths from taxes. And the timber nurseries of the West are already vast in extent. In some parts the first thing the farmer does is to plant the fast-growing cotton wood, and the next is to plant better wood to take its place. In the East, where timber has been more plentiful, and is soon to be more scarce than in the West even, and where more durable building materials are more cheaply produced and more needed, the subject has not received proper attention.

How to Lay out a City.—The "New York Times" argues that the right-angular plan has turned out as inconvenient as the cow-path system, and advocates for situations like New York, a main longitudinal avenue of great width, with rectangular and diagonal streets leading from it. There should certainly be some other means of getting from corner to corner of a series of square blocks, than going round the town or "playing a game of checkers" through its centre. Diagonal streets may yet have to be cut through our right-angled cities. Baron Haussman has spent 375 millions in altering the map of Paris, during the last fifteen years.

Power Looms were first constructed in England by Cartwright in 1787, and first started in this country on the improved plans of Moody, an American, by Lowell (after whom the city of looms was named) in 1815.

COMPRESSED SLACK COAL.

Mr. Warington W. Smyth's report on the art of mining and metallurgy at the Paris Exhibition.

Within the last few years, careful experiments, conducted by the administration, have proved, what was long doubted, that France possesses coals excellently adapted for sea service; and for some time past no other than French coal has been used in the Imperial navy. But for these purposes the fossil fuels from different localities have to be judiciously selected and mingled in certain proportions. Taking the coal as a whole, it is noticeable that it makes much more small and dust than our own, and is more frequently apt to be "dirty" or mixed with shale and clay. It hence results, that the French coalmasters have been driven to pay a special attention to methods of cleaning their produce and utilizing the "slack," *menu*, or small coal. At the great Exhibition in 1851, Bérard's coal-washing machine came before us as a novelty, although it was only in certain details that it could rightly be so considered; and, besides several contrivances for that purpose introduced more recently, a great variety of ingenious apparatus has been brought into use for making "patent fuel," *agglomeres*—that is, for pressing the small coal into cakes of various forms by the aid of a small amount of some binding material. These *briquettes* are highly reported upon for naval use; in their carriage to the ports there is a loss of only 1 per cent., against from 6 to 10 per cent. on lump coal; and when stored abroad they are found after two years' exposure scarcely at all injured, whilst ordinary coal would have suffered to the extent of 50 per cent. Moreover, they are free from ash, and may be made of a mixture of flaming and of dry coal, or of those varieties which have a more free-burning and a more calorific property respectively, in such a ratio as to give the best effect in getting up and maintaining steam. The late Exposition abounded with examples of the machinery and the products of this manufacture; and, although we are not in Great Britain without a similar industry, attention may fairly be called to the subject in the interest of the millions of tons of small coal and of inferior qualities which we are every year actually getting rid of as refuse.

As early as 1833, Messrs. Marsais and Ferrand took out a patent for this purpose, but it was not until 1843 that the agglomerated coal began to be produced in any quantity, and some more years elapsed before the machinery was so far improved by several different engineers as to lead to the present large scale of the manufacture. The St. Etienne Company, by introducing an enormous hydraulic pressure, need only to add $5\frac{1}{2}$ per cent. of pitch (*brai sec*) to solidify the mass. The stack of rectangular blocks left outside the St. Etienne shed in the "park," throughout the heavy rains in April, gave good testimony to the thorough compactness and durability which had been thus attained.

The greater part of the French makers appear to have adopted the circular arrangement of the Messrs. Revollier, and of Mr. Evrard and M. Dehaynin.

In this machine the cylinders are disposed as the radii of a circle, in which the slack, after being heated by a current of steam, and mingled by very ingenious apparatus with the pitch, is pressed by pistons and formed either into cylindrical or hexagonal blocks of convenient length. The rate of production appears to be in practice, 10 tons per hour with one machine, requiring an engine of 50-horse power to work it, and the extreme limit of pressure being 100 atmospheres.

The prices of the St. Etienne compressed fuel are high; the first quality, which contains only 2.10 per cent. of ash, is marked at 28 francs per ton; the second, with 5 per cent., at 26 francs; whilst the best block coal rules at from 19 francs to $23\frac{1}{2}$ francs, and the small at $9\frac{1}{2}$ francs to $15\frac{1}{2}$ francs. The very small proportion of gas, tar, or pitchy matter introduced into the mass at this work, can scarcely be considered as a general guide, since different qualities of coal will need some more and some less of binding material.

M. Felix Dehaynin, a producer of no less than 175,000 tons of *agglomeres* in the year, exhibited drawings of the Evrard machine as modified by himself, and employed at his three works, in which 500 people are engaged. The company called the "Ocean," at Paris, were also exhibitors of drawings and of the apparatus for the same purpose, known by the name of its inventor, M. Mazeline.

As an adjunct in these operations, an ingenious machine by Hanrez & Co. may be noticed. It is constructed for the dying of small washed coal by the revolution of a screw within a revolving perforated cylinder, and is stated to dry five tons per hour.

We could wish that coalworkers, mineral landowners, and capitalists, would note these various indications of what is now becoming in France an important trade. Without being unmindful that several companies have been established in South Wales and elsewhere for a similar manufacture, we cannot but be conscious that their action is but an infinitesimal set-off against the wholesale waste of slack that takes place in this country. It is not only that the small coal cut and broken from the salable part of seams is, in most of our districts, thrown into goaf and gob by the tens of thousands of tons, but those proportions of beds, often some feet in thickness, which are intermixed with stone or sulphur, or which make a larger than usual proportion of slack, are at once rejected as useless, and acres of such coal are abandoned to be inextricably mixed up with broken roof and heaving floor, although of no worse quality than would be turned to advantage in many a French colliery. It is impossible, in the hard competition of the times, to blame individuals for this sin against the economical use of Nature's gifts; but it is a discredit to the country at large, and will, among our descendants, entail many an anathema on the selfish stupidity of their forefathers. American miners take notice.

Electro-Plating iron with copper and brass is successfully carried on in France, in the following simple manner:—The iron object is coated with a varnish of resin, dissolved in benzine. This is then coated with plumbago, and the copper deposited as usual. By this means the peeling off of the thin layer of copper is obviated.

Saw Works.—Disston's in Philadelphia comprise 7 buildings, having an area of 500,000 square feet, and employ 400 hands.

THE INSTITUTION OF CIVIL ENGINEERS.

HISTORY OF THE SOCIETY—ITS NEW HOUSE IN LONDON.

Compiled from "Engineering."

Former Societies.—Although the Society of Arts was founded in 1754, the English engineers had no representative body, no arranged and adequate means for the communication of ideas, till much later. In 1768 Smeaton and a few friends formed a more or less convivial engineering club which met at the Queen's Head Tavern in Holborn, and lasted some 20 years, but left no professional records. In 1792 Smeaton was about to reorganize the society in a "better and more respectable form," but his death prevented. His friends, however, did reorganize it, and commenced a series of fortnightly meetings on April 15, 1793, at the Crown and Anchor in the Strand; there was better order, but not less eating and drinking. The "Smeatonian Society of Civil Engineers" still exists, and holds monthly meetings at the Freemason's Tavern during Parliamentary sessions, but its pith and sap have been absorbed by its single vigorous branch, the "Institution of Civil Engineers."

History of the Institution.—In 1817 William Maudslay, Henry B. Palmer, Joshua Field, James Jones, Joshua Collinge, and James Ashwell, formed a society and drew up rules which are still maintained with some modification. In 1821, Thomas Telford, appreciating the value of such a society, and foreseeing how it might extend in professional influence and power if well managed, accepted the presidency. In his inaugural he said that the institution had arisen from the wants of society, and being the result of its present state promises to be both useful and lasting. Under the able guidance and powerful influence of Telford the society grew and prospered. Its meetings were held at No. 1 Cannon Row, Westminster, till 1839, when it erected its present offices, No. 25 Great George Street. On the 3d of June, 1828, it obtained a royal charter, and was incorporated under the title of the "Institution of Civil Engineers." Telford's devotion to the interests of his protégé increased, as he gave up professional pursuits in his later years, and he remained president till his death in 1834. The second president, Walker, retained the chair for 10 years, and Sir John Rennie remained in office 3 years. The term of presidentship is now 2 years, and since Rennie, 11 members have filled the chair. At the present time the institution has 1,689 members, of whom 16 are "honorary," 641 "members," 909 "associates," and 123 "students."

New Building—Cost.—The insufficient accommodation of the old house led to inquiry as to the best site and plans for a larger building. An eligible site and structure in Victoria Street would have cost £26,000 to meet which the institution had the rent of the old house, £4,000, and £18,000 available property; this would have entailed a debt of £4,000. The old site, 25 Great George Street, sufficiently increased by the purchase of adjoining property, was therefore obtained at a yearly rental for 99 years of £659, with the privilege of purchase within 10 years for £12,000. The cost of the alterations and extensions of the building was £11,650. The architect is Mr. J. H. Wyatt; the contractors Messrs. Holland & Hannem.

Main Features — Rooms. — The main feature of the new design was the construction of an ample meeting room in place of the old cramped and awkward theatre 44 feet 9 inches by 24 feet 8 inches; the improvement of the library, and some means to avoid the undue crush of the annual conversazione. At the same time, the old façade and entrance were to remain. The original plans (see "Engineering," vol. V.) were reconsidered, and the present building is as follows:

On the left of the main hall is the secretary's room 24 by 17 feet, and a clerk's office 17 feet 7 inches by 15 feet. The two are separated by a glazed partition which can be removed upon occasion. At the end of the main hall, which is paved with tesselated marble, an archway under the main staircase, decorated with bronze gas standards and statuary, leads to the lobby leading to the council room, 21 feet 6 inches by 31 feet 10 inches, on the left, and the members reading and writing room, 40 feet by 28 feet 4 inches, on the right, and to the lavatories. On Tuesday evenings tea and coffee are served on a removable counter in the reading room, and on conversazione nights the partition between the reading and the council rooms will be removed, making a spacious refreshment room. At the back of the council room stairs lead to the kitchen below, and other stairs to the rear of the president's chair in the theatre above. In the basement, approached by a separate staircase, is the strong room, $12\frac{1}{2}$ feet by 7 feet.

The Theatre.—The main staircase, 4 feet wide, occupies a rectangular well 18 feet 6 inches by 21 feet, extending unbroken to the lantern above, 48 feet from the ground level. A rise of about 14 feet brings up to the level of the meeting-room or theatre on which the principal care of the architect has been expended. It has a clear area of 60 feet by 40 feet, with a height of 30 feet from the floor to the springing of the dome by which the room is lighted. There are four entrances, the doorways of which are handsomely executed in oak. The principal entrance opens from a 6-foot landing at the head of the main stairs, which also extends to the library. A second access is obtained on the extreme left, by a gallery, and is intended for the entry of members who arrive after the proceedings have commenced. On the right two more doors open from another gallery.

The arrangement of the seats in the theatre has been carefully devised. The President's chair occupies a point opposite the space between the central doorways, and from this, as a centre, a series of semicircular platforms have been laid, each tier from the council table to the opposite wall rising above the other, so that the outer row is about 3 feet from the ground. The objectionable plan of having a clear avenue down the centre of the room to the President's chair, a plan which invariably interrupts the attention of the meeting by the entry of late members, has been avoided. The circular benches, arranged upon the platform tiers, are placed 2 feet 7 inches apart from back to back, so that ample sitting accommodation is provided for 375 people, which the room is calculated to hold without a gallery. There is a small room at the back of the theatre, devoted to the use of diagrams, etc.

The sides of the meeting-room are treated with Doric and Ionic pilasters, terminating in sufficiently enriched cantilevers and cornices at the ceiling. The bays left between the pilasters will ultimately be filled with the pictures belonging to the Institution. At present, however, the only decorations will consist of brackets carrying the busts which adorned the old building. The principal of these is the marble bust of Telford, which will fill a conspicuous place in the library. Of the others, the main ones will be the portraits of Dr. Olinthus Gregory, Thomas Tregold, Professor Faraday, Sir Robert Peel, John Smeaton, Watt, Rennie, the Stephensons (father and son), Maudslay, the elder and younger Brunel, Locke, John Fowler, Hawkshaw, Joshua Field, Bryan Donkin, G. P. Bidder, and Rendel.

Lighting.—Eight lunettes—4 on the north and 4 on the south side of the meeting hall—aid the light thrown by a large central dome 19 feet in diameter, enclosed in an outer dome, so that the light is passed through a double medium. By night the theatre is illuminated by 3 sunlights; the central one in the middle of the dome has 63 lights, and the 2 side ones 28 lights each. Two grated openings are provided in the ceiling for ventilation.

Heating.—Thirteen grated openings placed around the room about 15 inches above the floor, and openings in the risers under the seats, admit the warmed air forced from the basement at the rate of 400,000 cubic feet per hour, being an allowance of 800 cubic feet per hour for 500 people. Fresh air is taken from without and carried along an underground channel leading into the basement. At the extremity of this channel a fan, driven by a 1-horse gas engine, forces the air into a chamber, where it is warmed in winter, and can be cooled in summer. The apparatus employed for warming the air consists of a series of hot water pipes, 4 inches in diameter, disposed in horizontal tiers, and so arranged that the entire volume of air used for ventilation must be passed amongst the spaces between them before it leaves the chamber. The axis of the fan used for forcing the air into the building is situated parallel with that of the air channels, and it carries two blades placed at 50°, the diameter being 3 feet. Means have also been provided for filtering the air before admitting it, and in summer a cold water spray will be forced against a fine wire gauze screen covering the mouth of the channel to cool the air on its passage. Valves are placed in the different branches to regulate the admission, and an independent coil is placed in the hall to warm the entry to the building.

Library.—In the library, 42 feet by 28 feet, the first and second floors of the old building have been thrown into one, and a gallery supported on brackets, is carried around the room at the old upper floor level; this gallery is wide enough to contain bookcases and leave space enough for stools and desks for readers. The library is illuminated with two 28-burner sunlights, and sufficient ventilation is secured by gratings in the ceiling. The top floor has been made into one spacious loft with an excellent light for the preparation and storage of diagrams.

Such is the house the Institution of Civil Engineers has built and garnished for itself in the fiftieth year of its life.

The Park Bank.—This showy, and in many respects splendid structure, occupying part of the site of the old museum opposite the Astor House, was opened in December. The façade is of white marble, richly decorated in the classic style. The striking features are the double rows of columns supporting the portico, the collossal statuary, and the lofty Mansard roof. The central hall, 12 ft. wide by 50 ft. long, leads to the banking-room, 56 by 90 ft., and 40 ft. high at the springing of the glass and iron dome. The decoration of the walls is Pompeian, and the effect of the warm tints is pronounced very fine. At the 4 corners are 4 medallions representing Art, Science, Industry, and Justice. The wainscoting is 5½ ft. deep, with stiles of dove-colored marble, and panels of reddish Tennessee marble. The screen is of bronze, with black marble shelves and plate glass windows. The desks and counters are of mahogany. The safes cover a space 20 by 7 ft., and are 13 ft. high. The room is warmed by a steam pipe running along the bases of the internal divisions, and a number of Gold's heaters. On 3 sides of the room are galleries 8 and 10 ft. in width; from 1 of them opens the book-room, 50 by 9 ft.; from another, the directors' room, 24 by 17 ft., decorated like the banking-room, and richly furnished. On the right of the main hall is the bank parlor, 48 by 20 ft., and 17 feet high. It is velvet carpeted, walnut-root wainscoted, Marcott decorated and furnished, and altogether princely. The space on the other side of the hall, and in the 2d story of the front building, is divided into spacious rooms for other banking and insurance companies.

The safety deposit vault in the basement of the building is built of granite blocks 2 feet thick, and contains 486 safes. The foundations of it form a mass of masonry 49 by 24 feet in plan, and 24 feet high. The front foundation wall of the building is 32 feet deep below the sidewalk, and from 8 to 11 feet thick. A 3-horse power caloric engine in the basement forces water 95 feet high to a 3,000 gal. tank. The building is essentially fire-proof. The floors are iron girders and brick arches.

The building cost $700,000 ; the lot $350,000. The architect is Mr. G. H. Thomas ; the builder, Mr. G. T. Smith ; the carpenters, Messrs. Smith & True. The statuary is by Mr. R. E. Launitz.

LOCOMOTIVES FOR HEAVY GRADES.

The system of locomotives for the Mont Cenis Railway is thus commented upon in "Engineering." The construction of a railway over Mont Cenis, to be worked until the completion of the great tunnel, was a work creditable in every way to English enterprise and engineering skill. But we cannot the less disapprove of the absurdly complicated system of locomotive power employed to work in it.

The gradients on this line are 1 in 12, and the gauge 3 feet 7 inches. Messrs. Fell and Alexander, engineers, have respectively reinvented and worked out the old Vignoles-Ericsson-Sellers system of mid rail and engines with gripping wheels —a scheme as needless as a fifth wheel to a coach. These engines have frequently broken down, and it has been sought to throw the discredit upon the French makers, MM. Gouin who are among the very first makers in France, whose work —and they have made nearly 1,000 locomotives—gives no trouble on other lines.

It is now understood that a totally new class of engines will be made for the Mont Cenis line by MM. Cail & Co., the eminent locomotive constructors of Paris and Lille. The horizontal wheels are to be co nected by spur gearing, and so driven by independent cylinders; whereas, in the present complicated plan, the 4 coupled driving wheels and the 4 gripping wheels are worked from a single pair of cylinders. The new engines, which have been designed by Mr. J. R. Crampton, will certainly be superior to those now on the line.

But our authority concludes the gripping wheels and mid rails unnecessary, for the following reasons : Inclines of 1 in $18\frac{3}{4}$ had been regularly worked for 6 years on the Virginia Central Railway, the engines drawing from twice to three times their own weight behind them. Inclines of 1 in 10 had been worked during the winter of 1852–53 on the Baltimore and Ohio Railway, the coupled engines, having the whole of their own weight available for adhesion, drawing a load equal to their own weight behind them. At the opening, too, of the Mont Cenis Railway, last summer, the engine went up with its train, drawing its assigned load by the adhesion due to its own weight, the "gripping wheels" not being put in action at all.

It is quite certain that the adhesion of the driving wheels on a clean rail is often from one-fourth to one-third, and in some well-attested cases even three-eighths of the weight, and it is abundantly capable of proof that an engine or steam carriage, with its whole weight and load available for adhesion, can ascend inclines of 1 in 12 in any and all weathers.

THE NITRATE STEEL.

The controversy regarding the Heaton process has overrun the columns of the engineering press, into the London "Times." The only conclusion we are able to draw from the great mass of matter published, is that Mr. Heaton's claim to have made soft, uniform, homogeneous rails and bars, without remelting the first product of the converter, conflicts with the chemical possibilities as we now understand them. Says "Engineering:" The highest chemical authority in the kingdom, Professor Miller, has analyzed the Heaton metal, from samples taken by himself direct from Mr. Heaton's converters and rolling mill, and has found, as was to have been expected, numerous and extensive impurities, which unmistakably indicate not only a variable, but a very inferior, if not worthless quality. One sample of "crude steel" had almost

3 per cent. of impurities, of which 1.8 per cent. were carbon. Another sample of this steel after it had been simply cut, piled, heated, and rolled, had nearly 2 per cent. of impurities with 1 per cent. of carbon. Any so-called steel made from highly phosphuretted pig, by a hasty boiling over nitrate of soda, including the incorporation into its own mass of a lump of cast-iron at the moment when the nitrate floats to the surface, could not possibly be expected to be uniform in quality, nor could it be expected to be of good quality in any case. A correspondent of the same paper says: The secondary or resultant product obtained by merely cutting, piling, beating, and hammering while in a spongy state, appears to have a wonderfully different chemical composition, one-half of the carbon being removed. This, it is tolerably certain, would not be the case with any other steel. A puddled steel, a crucible steel, or a Bessemer steel bar contains as much and no more carbon than the bloom, blister bar, or ingot from which it was made. But the secondary product of the Heaton process, although it is asserted to contain 1 per cent. of carbon, is nevertheless pronounced to be "malleable iron of the finest and purest quality." As to the authorship of the process, the authority first quoted says: Nor is Mr. Heaton even the inventor or discoverer of the use of nitrate of soda for purifying iron. He has invented merely a mode of using it, whereby it was kept or supposed to be kept at the bottom of the metal charge until the oxygen of the nitrate is given off. He first places the nitrate in the bottom of his converter, and to prevent it from at once floating to the top when the charge is poured upon it, he fastens it down by a cast-iron plate perforated with holes to allow the melted iron to obtain access to the nitrate, and to allow the oxygen thus evolved to rise.

This authority, however, does not attempt to *write down* the new process, but farther says: Mr. Heaton may be quite sure that his experiments in making steel from common brands of iron are watched with the greatest interest, and, so far as the iron trade is concerned, with all the hope that is possible in the face of so much conflicting evidence. If his assertions are true, he will, by another year, have added at least ten millions to the value of the iron now made in Great Britain, taking the value of his professed improvement at £2 10s. a ton only on 4,000,000 tons. His mode of treating melted pig-iron is much more expeditions than puddling, his plant is inexpensive, and the alleged increase of value of iron treated by his process is even greater than we have just estimated. A report to the Austrian government by Mr. Fred. Kohn takes an unfavorable view of the Heaton process, and in the matter of cost, states as follows: The difference between the price of phosphoric pig-iron and of pig-iron which is comparatively free from phosphorus, is about the same as the price of the nitrate of soda; it is therefore obviously simpler to purchase the dearer pig-iron, and to produce really pure steel from it, than to purify the inferior pig-iron in a certainly very incomplete manner, and to spend for the chemicals employed for this purification the whole balance derived from the difference in the prices of good and bad pig-iron.

The points in Mr. Bessemer's letter to the London "Times" are: 1st.—The inference to be drawn from a previous comparison of Heaton's and Bessemer's processes in the "Times" is that Mr. Heaton can by his process produce, from a cheap and inferior pig-iron, steel of a similar character to that obtained from a more expensive raw material by the Bessemer process. That is, however, far from being the case, for Bessemer steel is cast-steel—that is, steel made into a perfectly homogeneous mass while in a fluid state—and to that circumstance alone owes its great value as a material for the manufacture of railway bars, etc. 2d.—Whenever solid substances are converted into gas, a vast amount of heat is absorbed and rendered latent; hence in the Heaton process so much heat is abstracted from the metal in generating oxygen gas by the decomposition of nitrate of soda that the metal solidifies while in a state of mechanical admixture with the sand and soda, and thus, instead of obtaining fluid cast-steel by his process, Mr. Heaton obtains only a lump of spongy, porous metal, intermixed throughout with slags and scoria, and having the general characteristics and properties of ordinary puddled-iron or puddled-steel, but which is only obtained at a cost (for nitrate of soda) of more than double that of the ordinary puddling process. 3d.—The Heaton crude metal may, in common with puddled-iron of every description, be made into cast-steel by resorting to the old and costly Sheffield process of melting in crucibles, a process which consumes about $3\frac{1}{2}$ tons of coke for every ton of metal so melted, and with the additional cost of wages, crucibles, etc.; this melting process alone costs from £5 to £6 per ton. Hence, although Mr. Heaton starts with a cheap pig-iron, giving him an advantage of 20s. to 30s. per ton over the cost of the Bessemer raw material, he nevertheless employs for the conversion of 1 ton of pig-iron (according to Dr. Miller's report), no less than 270 pounds of nitrate of soda, which, at the present market price of 15s. per cwt., is equal to 36s. on the ton of crude iron, thus bringing up the cost of the materials employed in making 1 ton of crude steel by the Heaton process several shillings per ton above the cost of the high-class iron used in the Bessemer process; and we must add to the cost of the Heaton crude steel the additional cost of £5 to £6 per ton for melting.

In Mr. Heaton's reply the points are: 1st.—His plant is very cheap compared with Bessemer's. 2d.—The cooling effect Mr. Bessemer refers to is far outbalanced in his own process by the cooling effected in his converter by the prodigious volume of cold air forced through it for from 20 to 40 minutes. Which will carry off most heat, such a volume of air, or the oxygen evolved from 224 pounds of crude nitrate to the ton of steel? 3d.—Mr. Bessemer says his steel is a solid homogeneous mass, entirely free from scoria or other impurities, whereas mine is not, owing, he says, to the "mechanical admixture with the sand and soda." This is not the case. The slag, owing to its small specific gravity and to its extreme fluidity, rises to the surface of the molten metal, leaving the subjacent steel free from slag or scoria. It is not the fact that sand is necessarily employed; but were it so, the proportion of alkali is so great that the slag formed would be, and is, perfectly liquid, and is not mixed in any sensible quantity with the mass of steel in the converter, upon which it floats, as I have already observed. 4th.—As to the statement that "Heaton obtains only a lump of spongy porous metal, intermixed throughout with slag and scoria," he says: Steel from my converters passes at once either into my patent reverberatory furnace, or into a furnace of Mr. Siemens, and is kept in a molten state and thence run into ingots, as homogeneous and to the full as good as Mr. Bessemer's. Mr. Bessemer knows that his own steel has been proved by Mr. Siemens to be greatly improved by being thus kept for some time in fusion after it has been poured out of his converter as Bessemer crude steel. It is, therefore, not a fact that my "crude metal can be made into cast-steel only by resorting to the old and costly Sheffield process of melting in crucibles." 5th.—With reference to the nitrate employed: But the circumstances under which the experiments of Dr. Miller were carried on were purely exceptional, and the proportion of nitrate usually employed is not, as Mr. Bessemer states, 270 pounds, at a cost of 36s., but 224 pounds, at a cost of 28s. 6d., taking the extraordinary high prices of nitrate that at present prevail. Ten per cent. of nitrates is all that I have found necessary for the production of a ton of steel from inferior brands, and considerably less than 10 per cent. for superior brands. 6th.—As to quality, Mr. Heaton says: I have but just turned out 40 tons of steel rails direct from my converter, without any remelting, rails of a fine fracture, neither "fibrous" nor "laminated," but quite as homogeneous as Mr. Bessemer's, resisting the ordinary mechanical tests for steel rails, and produced at a cost with which no Bessemer steel can compete. Further, such orders are in course of execution.

To which Mr. Bessemer replies in another long letter to the "Times," substantially this: Heaton's apparatus is less perfectly developed, and therefore less costly, but 10 per cent. on the cost of the Bessemer apparatus does not amount to over 2s. per ton on the steel produced. As to the cooling action of the air, the heat actually produced in the Bessemer vessel is the most intense known in metallurgical operations. That the Heaton metal is not produced in a liquid state, and has therefore to be melted by another operation, in order to be as sound and valuable as Bessemer's, viz., *steel*, is officially stated by Dr. Miller in his report, and by Mr. Heaton. The former says, the product of the converter was poured on the floor in a pasty state, and then broken up and melted in pots. Mr. Heaton mentions, in his cost sheet, £5. 10s. per ton for remelting in crucibles. He also told Mr. Bessemer, as a reason why he should not be proceeded against as an infringer of the Bessemer patents, that he did not produce ingots of fluid steel by his (Heaton's)process. Mr. Bessemer admits that his own process could not make good steel from Cleveland iron, but states that the 65s. and 70s. pig that he does use, makes cheaper steel than the cheapest Cleveland pig + 28s. per ton for nitrates.

As to the invalidity of the Heaton patents for the use of nitrates, Mr. Bessemer replies at great length, citing some old patents;* and stating that he was himself the first to make steel by purely chemical means—by simply passing oxygen through the molten iron without the use of fuel, and that his patents claim the use for this purpose, of any oxygen-bearing substance. Mr. Bessemer says he has recently obtained patents for means of using the nitrates, in order to protect himself from farther inroads by Mr. Heaton.

Some tests have recently been made by Mr. Kirkaldy on a steel said to be Heaton's, the result being very uniform, and showing 23 tons tensile strength and 20 to 28 per cent. elongation in breaking. Mr. Heaton states that a remelted tool steel in one-half inch bars, from very impure Cleveland pig, stood above 53 tons. Some of the London authorities do not believe that these tests were made on the Heaton steel. Mr. Heaton's statements conflict with other statements previously published by witnesses of the process, and by the analyst of the product. Until the doubts thus thrown upon the process are explained away, it is impossible to believe that Mr. Heaton has as yet made any great advance in the manufacture of cheap iron and steel. We do not think, however, with some of our contemporaries, that the process is of no value because ironmakers have not yet taken it up. It is also possible that there is value in the nitrates as purifying agents. If so, it should appear that Mr. Bessemer's mode of applying them, described in the last number of this magazine, is more reasonable and hopeful than Mr. Heaton's.

*See Van Nostrand's Magazine, Vol. I., No. 1, page 77.

Engineering in the Mississippi Valley.—General Roberts, U. S. A., sets forth in a remarkable paper, that the dyking of the Mississippi is obstructing the creative laws of delta bottoms, by emptying into the Gulf the material that if spread over the land would improve its quality and raise its level. He proposes to feed the Mississippi from the great Lakes, by way of the Rum River and the Illinois River, and connecting canals, and to feed the Ohio from Lake Erie, by way of the Beaver River.

THE MONT CENIS TUNNEL.

PROGRESS OF THE WORK—ENGINEERING DIFFICULTIES—THE BORING MACHINES.

Perhaps no work ever undertaken by men was more daring than the attempt to pierce the Alps with a tunnel. Nature seems to have upreared these mighty barriers as if with the design of showing man how weak he is in her presence. Even the armies of Hannibal and Napoleon seemed all but powerless in the face of these vast natural fastnesses. But the barrier which man had scaled of old, he has now undertaken to pierce. And the work, bold as it seemed, is three parts finished.

The Mont Cenis Tunnel was sanctioned by the Sardinian government in 1857, and arrangements were made for fixing the perforating machinery in the years 1858 and 1859. But the work was not actually commenced until November, 1860. The tunnel—which will be fully 7½ miles in length—was to be completed in 25 years. The entrance to the tunnel on the side of France is near the little village of Fourneau, and lies 3,946 feet above the level of the sea. The entrance on the side of Italy is in a deep valley at Bardoneche, and lies 4,380 feet above the sea level. Thus there is a difference of level of 434 feet. But the tunnel will actually rise 445 feet above the level of the French end, attaining its height at a distance of about 4 miles from that extremity; in the remaining 3¾ miles there will be a fall of only 10 feet, so that this part of the line will be practically level.

The rocks through which the excavations have been made are for the most part very difficult to work, and largely consist of crystalized calcareous schist, much broken and contorted; through this rock run in every direction large masses of pure quartz. The perforating machines are calculated to work best when the resistance is uniform; and it has often happened that the unequal resistance offered has resulted in injury to the chisels.

But before the work of perforating began, enormous difficulties had to be contended with. It will be understood that in a tunnel of such vast length, it was necessary that the perforating processes carried on from the two ends should be directed with the most perfect accuracy. It has often happened in short tunnels that a considerable but not fatal want of coincidence has existed between the two halves of the work, but in the Mont Cenis tunnel any inaccuracy of direction would have been fatal to the success of the work, since when the two tunnels should meet it might be found that they were laterally separated by two or three hundred yards. Hence "it was necessary," says the narrative of the official survey, "to prepare accurate plans and sections for the determination of the levels, to fix the axis of the tunnel, and to 'set it out' on the mountain top; to erect observatories and guiding signals, solid, substantial, and true."

When we remember the nature of the passes over the Cenis, we can conceive the difficulty of setting out a line of this sort over the Alpine range. The necessity of continually climbing over rocks, ravines, and precipices in passing from station to station, were as nothing when compared with the difficulties resulting from the bitter weather experienced on those rugged mountain heights. The tempests which sweep the Alpine passes—the ever-recurring storms of rain, sleet, and driving snow, are trying to the ordinary traveller; how terribly they must have interfered with the delicate processes involved in surveying. It often happened that for days together no work of any sort could be done, owing to the impossibility of using levels and theodolites. At length, however, the work was completed, and that with such success that the greatest deviation from exactitude was less than a single foot for the whole length of seven and a half miles. Equally remarkable and extensive were the labors connected with the preparatory works. New and solid roads, bridges, canals, magazines, workshops, forges, furnaces, and machinery had to be constructed; residences had to be built for the men, and offices for the engineers; in fact, at each extremity of the tunnel a complete establishment had to be formed.

According to the latest advices the work proceeds at a rate fully equalling the original expectations of the engineers. Of 12,220 metres—the total length of the tunnel—no less than 8,958 have been completed. It is hoped that the remaining 3,262 metres will be completed early in the year 1871.—*Railway Record.*

With regard to the machines used in driving the tunnel, each is formed of a pair of bars, about 6 feet long, having between them the 3-inch cylinder by the piston of which the boring tool is actuated. The cylinder is not fixed to the frame-bars, but is capable of sliding on them, motion being given to it by a large worm at its hind end, which gears into racks formed on the inner sides of the frame bars. The cylinder is 3 inches in diameter, and its piston has a rod about 2 inches in diameter, there being thus but a comparatively small annular area on the front of the piston on which the air continually presses. At the hind end of the frame-bars of the machine is placed a miniature engine, worked by compressed air — this engine driving, through a bevel gear, a square shaft, which extends nearly the whole length of the machine above the boring cylinder. This shaft, by means of a cam, drives the slide-valve of the boring cylinder, and also gives intermittent rotary motion to the tool, and also the necessary advance to the cylinder as the hole is bored. By an ingenious automatic device, the worm is thrown out of gear when the cylinder cannot advance by reason of the hardness of the rock. Each boring machine weighs about 6 cwt., and as the wear and tear to which they are exposed is very severe, it is found necessary to keep from three to four machines in reserve for each one at work.

The boring bars are of various forms and diameters. The Z and double Z or crown borers are those most used, but for some kinds of rock other forms are found preferable. The holes are generally about $1\frac{1}{4}$ inch. in diameter. In working through some of the very hard quartz it was found that the shots flew back from the ordinary holes without producing any disruptive effect on the rock, and the plan was therefore adopted of first boring several holes 4 inches or 5 inches in diameter, and then disposing some ordinary holes round these. When the charges in the ordinary holes were fired, the portions of the rock between them and the central hole were blown out, and a cavity thus formed, around which other shot holes were bored. The borers used for the 4-inch and 5-inch holes are of similar form to smaller bars, and, like them, they are worked by the boring machines, but at a slower speed.—*Mining Journal.*

The line is now worked by a temporary railway (referred to in another column) over the mountain. This road is 48 miles long, passing over a summit nearly 6,000 feet above the sea, and has long stretches of gradients of 1 in 12, and curves of two chains radius. The gauge is 3 feet $7\frac{1}{2}$ inches.

LOCOMOTIVES OF THE METROPOLITAN RAILWAY.

Very different types of engines are required on the various lines in, about, and under London, but the conditions do not seem to have been equally well met by the different locomotive superintendents. On the North London, the passenger business is large, but the goods traffic is immense. Trains weighing over 400 tons are frequently run with, and compelled to keep out of the way of passenger trains. All the new engines are designed to work goods and passenger traffic alike, and they are, therefore, of the most powerful class, weighing 43 tons, and fitted with 17-inch cylinders, 24-inch stroke, and caring 160 pounds pressure. They perform their duties admirably, and it is difficult to see how they could be improved upon.

The engines of the underground railway have the Bissell bogies, which appear to answer their purpose very well. Whether it is or is not possible to dispense with bogies it is not easy to say, as the underground line affords very conflicting testimony. The engines of the Midland Company, to work their city traffic, are very similar to the standard type, with the exception that they have 6 instead of 8 weels; but their use has been protested against by the engineers of the Metropolitan line, on the ground that, owing to the comparatively long and rigid wheel base, they injure the permanent way. On the other hand, Mr. Fowler designed 6 coupled engines without bogies to work the St. John's Wood traffic, from which we gather that he did not deem a flexible wheel base essential; these engines, however, are more often found standing in their sheds than running. The Great Western Company, too, have introduced 6 coupled, 4-feet broad gauge drivers without bogies, which work regularly and give satisfaction. All the engines we have named are remarkable for the facility with which they start their trains and the shortness of the distance within which they attain their maximum velocity.

The Metropolitan Extension is worked by 3 different types of engines. One class, weighing 33 tons, has 6 wheels, 4 coupled, 16-inch cylinders, 22-inch stroke, and 5 feet 6 inch drivers. The trailing wheels are placed directly under a large tank, and fitted with Mr. W. B. Adams' radial axle boxes. These engines are used alike by the Great Northern, and the London, Chatham, and Dover Company. Both classes are run with either end leading, and for this kind of work they are not the best. The radial axle box is not well adapted for leading wheels, and the engines oscillate very much when running tank-end first. A greater defect lies in the fact that the tanks are so high that the drivers cannot see over them. This latter evil was felt so severely in the case of the London, Chatham, and Dover engines, that Mr. Martley has recently cut 1 foot or 18 inches off them with great advantage.

The next type of engine has side tanks and 6 wheels, 4 being coupled with 15-inch cylinders, 22-inch stroke, and 5 feet 6 inch drivers. They are good little engines, run steadily, and cost little for repairs; thanks principally to the considerable dimensions given to the machinery, which is unusually heavy in proportion to the diameter of the cylinders.

Lastly, the Metropolitan Extension is worked by small tank engines with outside cylinders, 15 inches diameter, and 22-inch stroke; 6 wheels, 4 coupled, and Beattie's patent boiler and fuel-heating apparatus. They are, in some respects, the best engines on the line. Though small, they get away quickly with their trains, make an abundance of steam, and are essentially more "lively" than any of their rivals. None of these engines appear, however, to be the best that could be adopted in working this line; they are all too large and heavy for the slow speed adopted on this line. With the exception of short inclines at the ends, the road is nearly level, and according to modern notions, without expressively sharp curves.—*The Engineer.*

ACCUMULATOR COTTON PRESS.

From a paper by Mr. Baldwin Latham, read before the Society of Engineers, Dec. 7.

While the cotton culture in India was in its infancy, the quantity produced was too small to create a demand for any special baling apparatus. Machines were sent out from England, but they were of a very primitive kind. Screw presses, something like those used for making cheese, were contrived. The next step was to work the vertical screws by bevel gearing and a winch. Then, as the cotton trade grew in importance, there was devised a number of inventions and contrivances, some by engineers and others by the cotton growers, whose ingenuity was stimulated by necessity. Levers, screws, and wedges were tried alone and in combination. The use of hydraulic pressure naturally suggested itself for trial, but it was not very successful; no very great power was obtained, and the process by pumping was slow. Gradually, improvements were made in the lever presses, and these were generally preferred. Some of them may be mentioned. A Mr. McComb took great pains to make a good baling machine, and patented several of his improvements. His cotton was forced up by two compound levers, drawn together by a chain worked by hand or steam.

Mason's press had somewhat the same principle of levers, but was worked in a different way. A horizontal engine drove 2 machines, the crank-shaft running right and left from the engine. By gearing, a shaft parallel to the crank shaft was driven at a reduced speed, and by means of right and left-hand screws on these shafts 2 powerful levers were drawn together and forced upwards against the follower of the cotton box. Both these presses are still in favor, and are used in considerable numbers. Hodgart's press embodies a very ingenious combination of hydraulic and lever powers. The process by pumping being in ordinary presses slow, it was here endeavored to reduce the quantity of water necessary to be pumped by having a ram of small area, and by multiplying the power so gained by the levers. This press, at its usual rate of speed, will pack 10 bales per hour, and it is possible to do 14; but this is too severe labor for the men. At the time of the Abyssinian expedition, hay was packed for the troops at the rate of 15 bales per hour; but this was an exceptional and extraordinary speed.

The Bombay Press Company uses Nasmyth's press, which is one of the best that has yet been invented. The pressure is effected by 3 hydraulic rams placed side by side. At the beginning of the stroke, while the cotton is in a pliable state, the power is applied by 1 cylinder only. Towards the end of the stroke, the other 2 rams are also set in motion, the 2 cylinders having been filled with water, so as to save time in pumping when the power is applied to them.

There are in America a vast number of inventions for all processes connected with cotton. Levers and screws, hydraulic and steam pressure, have been combined in many different ways, and with varying success. Wood is more used in America than in England in the construction of machines, and machines so made would not probably find favor elsewhere. Very likely English machines would be condemned there. As one of the incidents arising out of the war, when the Southern ports were shut out from the rest of the States, the blockade runners took over English made presses, and among others some of McComb's, but they found no purchasers. Every other detail of cotton packing is studied by inventors in the States, and the correspondent before referred to, says that there are some fifty different patents even for modes of fastening the baling hoops.

Mr. George Ashcroft has patented a machine in which he obtained the power of hydraulic pressure combined with rapidity. The first and easy pressure on the cotton was rapidly effected by a steam piston, only the final and severe pressure being given by a hydraulic ram. This press worked satisfactorily, and would probably have been pushed to success by the inventor had he not thought of something better, viz.: the application of the accumulator.

While in theory there is no limit to the force that can be exerted by hydraulic pressure, in practice the difficulties commence at a certain point. A maximum pressure of 2 tons to the square inch has been employed; but then it is necessary to have a large area of ram to obtain the required total, and to get this with 1 cylinder involves practical difficulties, which increase very rapidly with the diameter of the cylinder, viz., the risk of spongy castings and parts inconveniently heavy and difficult to transport. In Mr. Ashcroft's invention, the required area is obtained by placing 3 cylinders with 8-inch rams side by side, and these giving a total area of 150 inches, a force of 300 tons is produced.

The box in which the cotton is pressed is made entirely of wrought-iron, strongly framed, and the upper part of it, where the ultimate pressure is received, is of considerable thickness. This part of the box is planed all over, so as to present a true and smooth surface to the cotton. The doors are made so that 3 of the 4 sides can open. The "accumulator" is of the well known simple kind, consisting of a cylinder and ram, the latter supporting a weight box which moves up and down in guides. The 3 hydraulic pumps of equal size are driven by a pair of horizontal engines.

The mode of working is as follows: The house consists of a ground floor and two floors above. Upon the ground floor are fixed the steam-engine, the pumps, the press, and the accumulator cylinder. The framework of the press reaches through the floor to the top of the chamber above. In the uppermost chamber the loose cotton is stored. On the centre floor are the handles for working the valves. During the whole time of pressing and baling the cotton, the engines and pumps are at work. The accumulator box is forced up with a pressure of less than 1 ton to the inch. The men upon the top floor having placed the bagging in the box, and filled it with loose cotton, which they trample down, the men below push round the revolving boxes (a special feature of the invention), so that the cotton-filled box is over the rams. The boxes revolve upon a strong vertical column, the weight being taken on balls, which rest upon a collar. A portion of the floor revolves with the boxes.

The hooping irons having been placed in recesses at the top of the press, the engineer opens the valve which admits the high-pressure water to the rams. At once the accumulator descends, and the 3 rams of the press ascend, forcing the loose bottom of the box upon the cotton. But as the accumulator descends the pumps being still at work, they, in some measure, restore the height of the water column, and the accumulator ram gently ascends and descends as the water is thus withdrawn and restored. When the cotton is compressed upwards as tightly as the rams can force it, the engineer shuts the valve which admits the water from the accumulator and the pumps, and opens one which admits the water from the differential cylinder. By means of rams of different diameters, the pressure given by the pumps is in this cylinder multiplied. The superior power thus produced forces up the 3 rams, and with them the cotton, the last few inches of the stroke to the ultimate point desired. One of the doors of the box is then opened, the hoops are fastened, and then the other doors being opened, the water in the cylinders is let to waste, and the rams descend. The elastic cotton at once expands into the small distance allowed by the hoops, and with but slight assistance from the workmen the bale tumbles from the box and falls down a shoot to the floor below. Meanwhile the other box having been filled with cotton, it is pushed round into its place over the rams, and is in its turn subjected to the pressure of the water, and so the process is repeated without intermission.

The principle of the accumulator is well known, and for working cranes, opening dock gates, and many other purposes, has been in operation some time. It is probable that sooner or later some one would have applied it to baling presses, but at any rate Mr. Ashcroft has done it, and he only. Among the merits claimed for this machine are the following: The simplicity and smoothness of the process obviates the excessive wear and tear which is unavoidable in machines where the pressure is obtained by levers or screws. The friction on the packing leathers is extremely small. Great uncertainty existed until recently on this point, and all makers of hydraulic presses differed from each other on the subject. Professor Rankine gave 10 per cent. of the total load as the amount wasted by the friction of the leathers, but the whole question has been most successfully investigated by Mr. Hicks, of Bolton, who by his experiments, which are recorded in his admirable little treatise published last year, proves that the friction of the leathers on an 8-inch ram is about $\frac{1}{200}$ part of the total load, the decimal varying from .003 to .005 according as the leathers are more or less worn, and well or sparingly lubricated.

The revolving boxes are an ingenious part of the machine, and by their arrangement obviously save much time. Twenty-five or more bales can be packed and hooped per hour. In Alexandria the accumulator press is in full operation, and at Bombay also it is exciting much interest among the cotton merchants, some of whom are now in treaty with a view to its adoption there.

THE SUEZ CANAL.

From a letter to the London "Times," by Captain Macgregor, of canoe "Rob Roy" fame, we extract the following interesting facts and impressions: The Suez Canal Company have been fourteen years at work upon their gigantic labor, and they announce positively that the canal will be opened within a year from the present time (November, 1868). The canal is to be 100 miles long, and 328 feet wide (at the water's edge). The depth throughout will be 26 feet in the middle. The direction is nearly north and south, with a few turnings, but no locks or bridges. There will be a slight tidal current along it, but no one can say at what intervals. Already about 50 miles of the cut is filled with salt water, and is traversed daily by numerous small vessels and some steam-launches and mailboats. The sensation of wonder at the prodigious scale of the operations in progress increases day by day as one moves along what seems to be a wide river, with villages on the banks and smoky funnels and white sails on the surface. Of this 50 miles many parts are not wide enough yet for large vessels, and only a small portion is excavated to the full depth. The remainder of the canal is more or less dug out. While some parts are quite dry, others are put under water to moisten the sand; others have great blastings of rocks, and one long section of 20 miles has to wait until the sea is admitted into the great dry basin of the future lake.

The dredging machines are 40 in number, and each of them cost £40,000 (?). They deliver the sand to barges to be carried out to sea, or pile it upon the banks, in some places to a height of 50 feet. The expenses at present amount to £200,000 every month, and the work has already absorbed £8,000,000 sterling.

Port Said, the town at the north entrance of the canal, is built of wood, with wide, straight streets, and accommodates 6,000 people of every nation, but with the Greek and Levantine element largely preponderating. The two long piers that form the harbor are made of blocks of sand, cemented with lime (concrete); each block weighs 10 tons, and there are 25,000 of them.

Ismailia is a pretty town half-way along the canal, which here enters the Lake Timsah. Here the Arabs and their camels and the jackals of the Desert are alongside the steamboats, the whirring lathes and sounding forge-hammers of the company's workshops. A fresh-water canal comes hither all the way from Cairo, and then branches out north and south along the whole extent of the salt-water canal. The sweet-water canal is already a blessing to Egypt. It is from 30 to 40 feet wide, and boats with all sorts of cargoes are towed or sail through it.

During one day a violent gale swept across the canal. To look at the Desert was to see a vast yellow picture of men and camels dimly floating in a sea of sand without any horizon. The quantity of sand, whisked from the plain and cast into the canal-water by a wind like this will be a serious matter to deal with. One ounce of sand per square yard amounts to 500 tons on the whole canal, and the wind sometimes blows in this way for a month together.

At Chaloof I found 14,000 men at work. They labor very hard, indeed, running up the hill with baskets of sand on their heads. About 1,000 donkeys walk in long lines with neat mat baskets on their backs. In curious and close contrast to these simple carriers the mighty power of steam toils and puffs as it hurls up huge bulks of heavy clay, and it is, perhaps, only in Egypt one could see human and animal power exerted in such competition with steam power. The laborers are sent from all parts of Egypt. They must come, but they are highly paid—from 2 francs to 3 francs a day. Prices, both of labor and of food, have risen very much since the canal has been begun, but the supply of fish has rapidly increased. The salt water canal teems with fish.

At this, the Red Sea end, the works of the canal seem very far behind. The entrance port has all the obstacles of a shallow mouth, soft and shifting sand for bottom, and a crooked irregular tide eddying about in a most puzzling way.

When the passage from the Mediterranean to the Red Sea is open to the world it is intended to tow vessels through by tug boats working along a chain which lies at the bottom of the water. Steamers are not to be allowed to use their own paddles or engines for fear of damaging the soft sloping banks of the canal by the "wash" thus created. The difficulty of towing a vessel of 2,000 tons in this manner when the wind presses her to one side is an objection to which I have heard no feasible answer.

THE ITALIAN TECHNICAL COLLEGE of commerce is now organized, and will be opened immediately under the direction of Signor Farrara, a distinguished Sicilian gentleman, lately Minister of Public Instruction. This institution is chiefly intended for young men destined for the Consular service and for mercantile pursuits. The principal languages of Europe and the East, the various systems of banking, the principles of commerce, of exchange, of book-keeping, and of commercial law will be taught in it. The Venetian Provinces contribute toward its maintenance 40,000 francs a year; the city of Venice, the magnificent Foscari Palace and 20,000 francs a year; the Chamber of Commerce, 8,000 francs; and the Government, 10,000 francs.

THE KIRBY REAPER FACTORY of D. M. Osborne & Co., Auburn, N. Y., comprises 8 large buildings, employs 300 men, and turned out 5,300 reapers in 1868.

WORKING THE SOLAR RAYS.

The possibility—we are inclined on general principles, to say the probability—of utilizing the direct heat of the sun, as proposed by Capt. Ericsson, is the grandest scheme that science has presented to man. It should almost appear that the Creator has laid up a little condensed heat in the coal mines for our use during our school-time; a little condensed milk for our babyhood in science; and that when we are grown and learned, we shall draw power from its original fountain. The facts regarding the heat of the sun, as quoted and developed by Capt. Ericsson, together with the recently acquired and equally startling knowledge, that our garnered stores of power are not as eternal as the hills, render such a conclusion reasonable and hopeful.

Capt. Ericsson has not yet told us *how* he concentrates the solar rays, but promises to do so in due time; meanwhile, the experiments and conclusions referred to are interesting and may be thus briefly stated.

Sir John Herschel's experiments relating to solar heat, were conducted at the Cape of Good Hope. His apparatus consisted of a tin vessel $3\frac{3}{4}$ inches diameter, $2\frac{1}{2}$ inches deep, open at the top, and partially filled with water darkened with ink. This was exposed to the immediate action of the rays of the sun in a stationary position for 10 minutes. The amount of radiant heat communicated was deduced from the increase of temperature of the water during the 10 minutes' exposure to the oblique rays. Owing to changes in the atmosphere, the elevation of temperature was not quite alike at each trial. Adopting the mean, he calculates that, near the earth's surface, the energy of the sun is such that the radiant heat is capable of melting an inch thickness of ice in 2 hours, 12 minutes, 42 seconds.

M. Pouillet's experiments relating to solar heat, like those of Sir John Herschel, had reference only to very low temperatures, the range of the thermometer scarcely reaching 60° C. The apparatus he employed was very similar to that of Herschel. It consisted of a cylindrical vessel of silver, 1 decimetre in diameter and 15 millimetres in depth; but being provided with a close top, it admitted of being fully charged with water, besides admitting of an inclined position, which permitted the rays to act perpendicularly on the blackened metallic surface. The disadvantages attending oblique action, not to mention the intricate question of *evaporation* during the trial, were thus avoided. A thermometer was inserted in the fluid, and means provided for proper agitation during the trial. The exposure to the sun was limited to 5 minutes, and the elevation of temperature during that brief time formed the basis of all his calculations.

These experiments, although interesting, are not satisfactory, as they deal with low temperatures. The purpose of Capt. Ericsson, on the other hand, has been to ascertain what amount of heat can be developed at the high temperature obtained by concentrating the solar rays, viz., bringing their power to bear on a reduced surface, and to devise the most efficient means for effecting such a concentration of the radiating heat. His experiments made under temperatures varying between 212° and 480°, and continued during nearly a year, tend to show that the problem cannot be solved by 5 and 10 minutes' trials restricted to temperatures some half-dozen degrees above that of the atmosphere. The results recorded by Pouillet, reveal discrepancies pointing to atmospheric influence, which, when properly understood, will modify the conclusions hitherto so confidently drawn.

Regarding the main result of the investigations of Herschel and Pouillet there can be no doubt. A body presenting a square foot of surface perpendicularly to the sun at noon, during summer, will, under favorable circumstances, receive about 5 units of heat per minute. This fact Capt. Ericsson has fully proved by concentrating the radiant heat of sunbeams of various sections from 650 to 5,180 square inches, hence fully 500 times more powerful than the sunbeams to which the "actinometer" and "pyrheliometer" have been exposed.

Investigations conducted only during the *summer* being insufficient to settle the important question, Capt. Ericsson is making a series of experiments this winter, with instruments so contrived that the loss of heat by radiation will be almost inappreciable. It is hoped, therefore, that a satisfactory explanation of existing discrepancies will be furnished. In order to facilitate these investigations, a small observatory has been erected over a building some 60 feet above ground, turning on a pivot by mechanism resembling that of a monitor turret. Still further to facilitate the work, the tables which support the instruments have been provided with mechanism by which they are kept perpendicular to the central ray of the sun during the experiments.

Capt. Ericsson's conclusions as to the power of the sun's rays are as follows: At the high temperature requisite for steam-engines, the heating power of the sun on a surface of 10 feet square will evaporate on an average 489 cubic inches of water per hour, by means of his mechanical contrivance for effecting the necessary concentration. This evaporation demonstrates the presence of sufficient heat to develop a force capable of lifting 35,000 pounds 1 foot high in a minute, thus exceeding 1-horse power.

The mean distance from the centre of the sun to the earth being 214.44 times greater than the radius of the former, it will be found by squaring this sum that 1 superficial foot of the sun's surface must heat 45,984 superficial feet of the earth. In other words, the sun on an equal surface throws off 45,984 times more heat than the earth receives. We are therefore enabled, on the strength of the practical result now positively established, to infer that an area of 10 feet square on the sun's surface developes heat enough to actuate a steam-engine of 45,984-horse power, demanding a consumption of more than 100,000 pounds of coal every hour. But as one-half of the heat conveyed by the solar rays is lost during their passage through the atmosphere and through the apparatus by which the temperature is elevated to the necessary high degree, the actual development of heat, on the supposed 10 feet square of the surface of the sun, will therefore equal the amount of heat generated by the consumption of 200,000 pounds of coal per hour.

In pointing out what amount of mechanical power may be obtained by occupying a Swedish square mile with solar engines, Capt. Ericsson assumes that one-half of the area is set aside for necessary roads, houses, etc., an available area would remain of $18,000 \times 36,000 = 648,$-000,000 superficial feet on which the radiant heat might be concentrated. His experiments having shown that the concentration of the solar heat on 100 square feet of surface is more than sufficient to develop a horse power, it follows that 64,800 engines, each of 100-horse power, may be kept in motion by the radiant heat of the sun on a square mile, or that the sun's rays which now waste their strength on the house-roofs of Philadelphia, would be able, if condensed, to set in motion 5,000 steam-engines, each of 20-horse power.

As to practical results Capt. Ericsson says: It is true, that the solar heat is often prevented from reaching the earth. On the other hand, the skillful engineer knows many ways of laying up a supply when the sky is clear and that great store-house is opened where the fuel may be obtained free of cost and transportation. At the same time a great portion of our planet enjoys perpetual sunshine. Capt. Ericsson had at the beginning of the last year constructed 3 different motors, called *solar engines*. One of these is actuated by steam formed by the concentration of the heat of the solar rays, while the other 2 are actuated by the expansive force of atmospheric air, heated directly by concentrated radiant heat. Some of his more recent experimental engines, the working cylinders of which vary from 2 inches diameter to 5 inches diameter with 6 inches stroke, are operated by atmospheric air heated to a temperature of 480° by concentrating the sun's rays; others are operated by steam of much lower temperature generated likewise by concentrating the radiant heat. The speed attained has in no case been less than 100 revolutions per minute, while a regular and continuous rate of 300 revolutions per minute has been reached. The construction of these experimental engines, present no features of special novelty. The mechanism, however, adopted for concentrating and transmitting the solar energy to their working pistons, is peculiar, and at the proper times, plans and descriptions will be published.

Excelsior Machine Works, Chicago.—These works employ 75 men on wood work and wood working machinery. The principal building is 270×60 feet.

The Charleston Phosphates.—The "New York Tribune" of Dec. 19, has an exhaustive article on the history and utilization of this important discovery. The "fish bed of the Charleston basin," so called because of the remains of marine animals found in immense quantities there, crops out on the banks of the Ashley river near its mouth, and on various neighboring rivers, and extends inward 40 or 50 miles. The marl or conglomerate of this basin is already ascertained to be 12 feet deep in some places, and to contain as much as 67 per cent. of phosphate of lime in some instances. Although its existence had long been known, its value was not ascertained till after the war, and even then it was difficult to enlist Southern capital in it. The necessary aid was obtained in Philadelphia, and now 5 companies with ample capital are mining the rock, and manufacturing the phosphates for agricultural purposes. The credit of discovering the value of the deposit, and of persistently calling attention to it, seems to be due to Dr. N. A. Pratt of Charleston.

Temperatures of various substances, superheated steam for instance, may often be conveniently ascertained by the melting points of alloys. The following are the fusing temperatures of various alloys of lead and tin:

Lead.	Tin.	Centigrade.	Fahrenheit.
7 parts.	4 parts.	213°	416°
7½ "	4 "	221	430
8 "	4 "	225	437
8½ "	4 "	232	455
10 "	4 "	241	466
14 "	4 "	252	484
19 "	4 "	262	504
30 "	4 "	274	524
48 "	4 "	275	544
55 "	4 "	289	553

Linseed oil boils at 312.40°.
Lead melts at 319°.

Schools in Chicago.—They are as follows: a high school, 21 grammar, and 6 primary schools, which are public; also some 50 private grammar schools, various Roman Catholic, medical and law schools, and the Chicago University. The number of scholars in the public schools in 1867, was 30,000, the total cost per scholar, $23.84, the number of teachers 401, the value of public school buildings $800,000.

COMMUNICATION BETWEEN ENGLAND AND FRANCE.

A new impulse has been given to this ever-recurring question, by the fact that a French port was recently unable to give shelter to a mail steamer bound for the shores of that country, and which, after beating about the Channel for twelve hours, was compelled to return to the harbor from which it started. The various plans put forward for better communication, are classed by the "Mechanics' Magazine" under one of three heads —submarine, transmarine, and supermarine. Under the first are included the tunnel and the tubular projects, the difference between them being that the tunnel whether of iron, masonry, or brickwork, must be placed in the earth, whereas the earth must be piled around and on top of the tube. The tunnel must be excavated or laid under the earth; the tube lies along the surface constituting the bed of the Channel. The object of the covering of earth over the tube in either instance is the same, viz., to preserve the top from being injured by ships' anchors, dredgers, sunken vessels, or other external disturbances. Of these two methods, the tube would probably have the advantage in point of time, but great difficulty would attend the junction of the several lengths. The transmarine classification embraces two plans,—that of a solid embankment and that of a gigantic ferry. A solid embankment, as it must be sufficiently high to be above the level of the greatest wave, partakes of the nature of the third class, and might also with propriety be termed intramarine. This plan is altogether Utopian. Neglecting aerial means of transit, a bridge is the sole representative of the third category.

The objections to the tunnel and tube are, the unsubstantial character of the scheme, the complete uncertainty of the time to be occupied in its construction, and the total want of precedent. Assuming that everything proceeded as favorably as possible, it would take nearly twenty years to finish the job, calculating that the rate of progress could not be greater than that at present obtained at Mont Cenis. On this subject "Engineering" says: "Setting aside the difficulties of such a work, the inextricable complications which would arise between the two countries in the event of the peaceable relations between France and England being interrupted, and the precarious length of life of the tunnel if completed, the length of time its construction would involve, the enormous outlay of capital, and the enormous loss upon locked-up money lying idle during the formation of the work,—each of these reasons is sufficient to dispose of the tunnel question forever. Moreover, during the 20 or 30 years such a scheme would require for completion, the necessities of the increasing traffic would certainly be satisfactorily accommodated, and the millions expended upon the tunnel would have been literally thrown into the sea."

The ferry scheme of Mr. John Fowler is as follows: It is proposed to construct at Dover a harbor of about 24 acres extent, protected on the east by the old pier, and on the south by a new pier carrying a railway. A suitable harbor would be constructed at Calais or more probably near Cape Griz Nez, where there is deeper water. The vessels to be 450 feet by 85 feet over all, and 53 feet beam, and to draw 12 feet. The engines to be 1,200 nominal horse-power, and the speed some 20 miles an hour. The trains are to be run bodily upon the boats, as in the American system. Four vessels, costing £120,000 each, are contemplated. Of this scheme the "Mechanic's Magazine" says: What is required is a connecting link between the two shores which is totally independent of the intermediate barrier, and this result is manifestly not obtained by the agency of a ferry. It is an alteration of the present arrangement in degree only, not in kind. For a time it would be considered a great boon, but so soon as the novelty had worn off, the feeling would arise that it was, after all, but a makeshift—a temporary expedient—and we should return to the reconsideration of the more permanent systems now claiming public attention.

Of the bridge scheme, the same authority says: Allowing about 1,000 feet for the width of the spaces, they would be, in round numbers, double those of the Britannia Bridge, while the height of the piers above high water would be but a mere trifle in excess of the Britannia piers. Every engineer will admit that the difficulty is not in the superstructure, but in the foundations ; but from the result of borings recently made, the substratum appears to be favorable to their being got in. And whatever circumstances of foundation and soil favor the construction of a tunnel, are doubly advantageous to that of the bridge, and, consequently, if no difficulty is to be experienced in that respect for the tunnel, the argument against the difficulty of getting in the piers falls to the ground. When lighthouses, constructed entirely of iron, and supported upon iron piles, have been erected far out at sea, it is absurd to talk of the great and almost insuperable difficulty of getting in foundations elsewhere in similar situations. Besides, it would not be all the piers that would give the same degree of trouble, but only those situated remotely from either shore. Another advantage of a bridge would be that its construction and its utilization could proceed *pari passu,* and there would be no necessity for waiting for its completion, as in the case of a tunnel, before its services could be availed of. As each successive span commencing from the shores was finished, it could be used as a jetty, and year by year the opposite coasts would be in closer contiguity. In adopting the project of a bridge, there is not the slightest necessity for departing from any of the recognized types of construction, either in the sub or superstructure.

The proposal lately put forward by a French engineer, Boutet—and given place to in such publications as the "Journal of the Society of Arts" and the "Pall Mall Gazette"—the scheme of floating foundations and spans of a couple of miles, is simply a chimera, and would not stand the test of theoretical, much less practical analysis. M. Boutet, says "Engineering," "proposes to cross the Channel from the Shakspeare Cliff to Cape Blanc Nez, by a bridge with 10 openings, or clear spans, each 3,282 yards long, the platform of which is to be 360 feet above the average sea level. He proposes to construct his 9 iron piers upon the shore, to float them into place, fastening them to the bottom with screw-piles, and covering the structure with gutta-percha to prevent the adhesion of barnacles and the deterioration of salt water. And he proposes to lay out the course of the bridge to which the piers are to be hauled and sunk, by a buoyed rope, stretched from France to England. From this range of stupendous summits, nearly two miles asunder, M. Boutet stretches cables 2 inches in diameter, and of iron, not steel ; from 30 to 120 of these cables are ranged vertically 20 inches apart, the larger number over the piers being reduced to the lesser in the centre of the span. The cables are woven together with smaller diagonal wire ropes, and cast iron is thrown in when it is of no service, because, we presume, it looks well in the drawing, and gives an air of security to the flimsy web. The lower side of this "tress," as the projector terms it, is curved, but there is no compression member designed, and, moreover, none *could* be designed which should resist the enormous strain of the structure, and give the only value which could be given to the rest of the clumsy contrivance. More than that—and this is a point which the dullest disciple of Boutet can understand—the projector proposes to give rise to these trusses of 6 in 1,000, and so to obtain an increased rigidity. Now, it is absolutely impossible to stretch a wire between two points, however close they may be together, without deflection, because the strain required to do so is infinite, and in such an extreme case as M. Boutet proposes, the cables would break from their own weight long before any approximation to a horizontal line was obtained. In fact, allowing the extreme amount of strength to his cables, and assuming that they could be made perfectly homogeneous throughout, it will be found that the strands would part in the centre before they were within 500 feet of a horizontal line, in other words, the point of rupture would be attained when the cables had still to be hauled up 500 feet to get them into position."

Some reasonable sort of bridge, however, would appear to be the only feasible continuous work that could be built. It would cost perhaps twice as much as a tunnel—the rule of cost is stated to be three times as much for bridges as for tunnels—but it would be completed in a reasonable time. Thousands of men could work upon it, while tens of men were at work on a tunnel.

But before the bridge question is settled, years before the bridge is completed, the comfort of millions of passengers is to be secured, and the transhipment of millions of packages of goods avoided, at a comparatively small expense, by the running of suitable boats between England and France. Undoubtedly the ferry system, however complete, will be inadequate 10 or 20 years hence; but during that period there should be at least as decent, comfortable, and economical communication as there is, for instance, between New York and Newport—a longer, and in parts more exposed route than that across the Channel.

Lead in Tin Vessels.—A report has been published on the tin and tinned vessels used in the military hospitals in France. The metal used for tinning, it was found, contained from 25 to 50 per cent. of lead. In vessels reputedly made of pure tin, the Commissioner found, in some cases, as much as 15 per cent. of lead. Such proportions are dangerous, he says, to the public health, and the Government is recommended to fix a standard allowing only 5 or 6 per cent. of lead to be used with tin in utensils intended for culinary purposes, or for drinking-vessels. The author has probably over stated the dangers from the use of utensils composed as he has found; but it would be well if cheap manufacturers in this country would bear in mind that it is not altogether safe to use a large proportion of lead.

Explosions in gas works, and in buildings where gas is leaking, as well as in mines, may be prevented by the use of the Davy lamp. Explosions are often caused in dwellings, by looking for leaks in meters and pipes with an uncovered lamp. At New Village, Mass., five men were recently killed by the explosion of a gas holder which they were repairing. The Davy or the Strive safety-lamp should be kept ready for use in gas works, and in all large buildings, such as hotels and theatres, where gas leaks are likely to occur.

Pratt, Whitney & Co.'s Machine Works, Hartford, Conn.—The machine shop is 220×45 feet, 3 stories, and employs 150 men. Machinery to turn out 500 rifles per day has recently been completed for Austria.

CONCREVE BUILDINGS.

Compiled from the "American Artizan," "The Engineer," etc.

The increased cost of building materials, has of late led to renewed and extensive experiments with concrete. This material has in various forms been employed for ages, and is said by travellers to be found hard and undissolved after 3,000 years of exposure among the temple ruins of Nineveh.

This concrete was in all probability composed simply of a lime mortar, tempered by treading with the naked feet of the laborers until it became tough and homogeneous, and then mixed with broken stone or rubble.

Many attempts have been made in this country to use a material of this character in the construction of buildings, but owing to the slight degree to which the management of the material in large masses has hitherto been understood, it has in many instances cost quite as much as brick; the comparative slowness with which the water is eliminated renders the wall liable in our northern climate to be suddenly disintegrated by frost. Because concrete has answered well in foundations, the conclusion has been too hastily arrived at, that it would therefore be equally suitable for houses. The duty it has to perform in the former case is to transmit the superincumbent pressure to the ground; and the only resistance that the material is called upon to display, is that against crushing. To secure rigidity and stability in unsupported walls, requires peculiar care and knowledge in selecting and compounding the materials. All artificial monolithic masses labor theoretically under the common disadvantage of their soundness being in the inverse ratio of their size. Not only is this true for artificial, but also for natural substances. These facts have led to the disuse of concrete for binding rubble into the form of walls, and the adoption of building blocks which are made of such size that one man may readily handle them, and which are simply bricks of concrete. This system also allows of the introduction of "bond," which does not, strictly speaking, exist in the rival principles, and there is, therefore, the absolute necessity for introducing binders, and joists, as soon as possible, in their case. The composition of these blocks differs from that of the ruder concrete in the addition of hydraulic or Roman cement, by which their hardening is much facilitated. The blocks are formed in wooden molds, and require in their manufacture only a moderate degree of skill, the material being made by combining, in a wet condition, caustic lime, cement, and sharp sand in about the proportions of 1 bushel of lime, 6 of sand, and 4 quarts of cement. The blocks require considerable time to harden solidly throughout, and should be kept under shelter. Some manufacturers facilitate the manufacture, and also the hardening, by mixing the ingredients by machinery, by means of which steam and hot water are injected into the plastic mass while mixing.

Recent experiments by a German investigator seem to show that the costly hydraulic cement may be dispensed with, when the blocks are not placed under water, by employing a kind of mortar made of slaked lime and finely sifted sand. Caustic lime, equal to $\frac{1}{4}$ of the sand used, is mixed with the mortar when required for use; the heat resulting from its addition induces the formation of silicates, which quickly harden the mortar.

It has been suggested that, inasmuch as the hydraulic cement heretofore so largely employed, owes its efficacy to the silicate of alumina contained therein, an artificial cement may be made for the purpose, by properly mixing lime with 20 per cent. of dry clay.

A modification of the "block" system, is the slab system. The difficulties attendant upon it appear to be, principally, the impossibility of ensuring the perpendicularity of the upright portions of the house, the squareness of the angles, or the sharpness of the arrises. The idea of attempting to raise walls 20 feet and 30 feet in height, by means of small angle iron uprights and slabs of concrete, from 3 inches to 4 inches in thickness, is a simple absurdity. The house consists of nothing but panelling, and one is puzzled to decide whether one is really inside or outside, as the walls appear to have literally no consistency or solidity.

For facilitating the construction of solid concrete buildings, a Mr. Drake has taken a patent in England, for the use of flanged iron plates, supported by iron uprights secured against the face of the wall, such plates to be shifted upwards step by step upon the uprights, and locked to them in the several positions by pins. He also claims angle plates to form the angles of walls ; also the use, to connect the front and back plates and uprights, of metal straps with pinholes in them at various distances, so that the length may be adjusted to the thickness required.

Several extensive structures are now erecting in England by the solid method, among them a large warehouse in London 70 feet by 60 feet by 50 feet, which will no doubt prove a success, because the work is carried on under the superintendence of those who thoroughly understand the subject, both theoretically and practically. The Duke of Northumberland is constructing a solid cottage of Portland cement concrete. The foundation set on sand, is 6 inches thick and 18 inches wide ; the walls are 9 inches in thickness and 2 stories in height. The roofs are all flat, and are constructed entirely of concrete and old wire rope. The ceilings are divided into panels by ribs at right angles, and require no plastering. A wall on the upper floor is supported on a concrete beam, 13 feet span ; a large cistern is formed under the roof, its sides being the walls of a room ; this will severely test the impermeability of the material. No wood is used except for doors, and no iron, except the old wire-rope.

GOLD AND SILVER.—A recent estimate makes the total quantity of gold, in the form of coin, jewellery, vessels, utensils, in fact in all shapes, in the hands of man, equal in value to £1,200,000,000 sterling. This would be 300,000,000 ounces, or 30,000,000 cubic inches. If converted into a single block, its dimensions would not be less than 26 feet square, and its weight 10,500 tons. In the shape of sovereigns placed in a single line on the ground, each coin being in contact with its neighbor, £1,200,000,000 sterling would form a track 4,300 miles in length.

The value of the silver in use is set down at £1,000,000,000 sterling in value. This, in round numbers, would be 4,000,000,000 ounces, or 400,000 cubic feet, measuring 100 feet square by 30 feet in height. In the shape of shillings, placed in contact and in line, the globe itself would be more than twice encircled by this amount of silver.—*Mechanics' Magazine.*

WATER-SUPPLY FOR CITIES.

IMPORTANCE OF PURE WATER—SEWAGE—ARTESIAN WELLS—PARTICULARS OF EXISTING WORKS—PUMPING MACHINERY.

From the excellent report of Chas. Hermany, Esq., Chief Engineer of the Memphis Water Works, we compile the following considerations and facts on this subject, and they are especially interesting and important to the inhabitants of towns not yet well supplied with pure water:—

One of the first and leading considerations in the selection of abiding places for man, whether it be the cave of the savage, the hut of the barbarian, the cottage of the peasant, the camp of the soldier, the residence of the man of wealth, or the site of a large city, is the supply of an ample quantity of pure and wholesome water. Nature, however liberal, does not always make ample provision for supplying the wants of man, inasmuch as springs, brooks, and rivers are not sufficiently numerous to furnish water of suitable quality *everywhere* where man chooses abiding places; hence his ingenuity or constructive ability is called into action, and wells are formed by excavations in the earth from which water is obtained for limited numbers in localities more or less remote from natural water-courses.

Quality of Water.—In cities where large populations dwell upon comparatively small areas of land, this mode of obtaining water fails, both as regards quantity and quality. Upon the sites of many towns and cities, wells wholly fail to furnish water of suitable quality; hence rain-water cisterns, constructed under ground, and located in streets, courts, alleys, yards, basements, etc., into which that portion of rain falling upon the roofs of the houses, and not evaporated or absorbed, is conducted and stored for use. These modes of water-supply are very expensive, considering the limited quantity and deteriorated quality furnished. The principal cities of the United States, in times of sickness or epidemics, had the *prevailing diseases* to much greater extent, and much more aggravated cases, by virtue of the fact that limited quantities of indifferent or bad water aided climatic causes in developing and prolonging epidemics. In the city of New York, as early as 1798, while the necessity of a supply of pure water was already severely felt, Dr. Brown, in a report upon the subject in the same year, "exhibits circumstantially the consumption of water as of a very small quantity (on account of the difficulty of procuring it), and subordinate quality; he considers this as the cause of a variety of diseases and contagious disorders, especially the yellow fever, which had recently made great ravages there. He also considers the state of health of a populous city as depending *more upon the purity of its water* than the quality of all the rest of its provisions together."

In the city of Philadelphia, as early as 1793 or 1794, Benjamin Franklin was, it is believed, the first who publicly called the attention of the citizens to the subject of watering the city from some other source than the wells then universally used; urging that the afflictions from the ravages of contagious diseases rendered it necessary that a more copious supply of water should be procured, to insure the health, comfort, and preservation of the citizens. This was just after the city had been visited by the yellow fever. And in Franklin's will, dated June 23, 1789, is the following clause: "and having considered that the covering of the ground plot of the city with buildings and pavements, which carry off most of the rain, and prevent it soaking into the earth, and renewing and purifying the springs whence the waters of the wells must gradually grow worse, and in time be unfit for use, as I find has happened in all old cities, I recommend that at the end of the first 100 years, if not done before, the corporation of the city employ a part of the £100,000 in bringing by pipes the water of the Wissahiccon Creek into the town, so as to supply the inhabitants."

To sum up all the advantages from a properly devised public water-supply, would require a lengthy dissertation upon the subject; we will therefore briefly enumerate some of the principal ones only.

1. It furnishes a better quality of water than is possible from wells and rain-water cisterns, and at a much cheaper rate for the same quantity than can be obtained by private or individual means of supply.

2d. It encourages a liberal use of wholesome water by all classes, and thereby induces habits of cleanliness and comfort, diminishes sickness, and in times of epidemics it has proved by the experience of other cities to be the greatest protection to densely populated districts.

3. By the constant command, at all hours of the day and night, of an unlimited quantity, for protection against the ravages of fire, it reduces the risks for insurance companies, and with that the rates of insurance, and in this way, perhaps more than in any other, is a well-regulated public water-supply productive of pecuniary advantages, which annually amount to a very liberal percentage on the capital invested.

4. It invites settlement, and encourages the investment of capital in manufacturing enterprises, which, by fostering productive industry, tend to build up the city in the elements constituting permanent wealth and independence.

As to the quality of the sources of supply, the report says: All the natural water-courses in every country become more and more impure with the increase of population, and less suitable for distribution in densely populated cities; and the best practice of hydraulic engineering, in its application to public water-supplies, is to collect and store the water as near as practicable to the gathering grounds, upon which it falls in the shape of snow and rain, and thence convey it artificially to the place of distribution. The truthfulness of this is illustrated by the following-named examples of water-supplies to towns and cities in the United States, where the water is collected and stored in reservoirs near the limits of the drainage areas supplying them, viz.: the Boston and Charlestown water-supplies in Massachusetts; the Albany, Croton, and Brooklyn water-supplies in New York; and the Hartford, Ct., and Baltimore, Md., water-supplies. The last two of these have changed within the last few years from taking their daily supplies from natural water-courses to storage reservoirs approaching the limits of the drainage areas supplying them with water. The Loch Katrine scheme, supplying the city of Glasgow; the Rivington Pike scheme, supplying Liverpool; the Birmingham water-supply; and the contemplated change in the mode of supplying the city of London with water, are cases in point, and demonstrate the justice and propriety of this view of the subject.

SEWAGE.—As the congregation of large numbers of human beings upon comparatively small areas has been shown to defile the spring and well water, as also the rain-water, by causing it to absorb in its fall the noxious gases which constantly arise from populous cities, as well as from the washings of the roofs, consisting of an almost endless catalogue of articles prejudicial to health, thereby compelling a supply being obtained from a source beyond the reach of city defilement, it must not be concluded that with the procurement of pure water the evil is remedied; it is only one of the effects which is obviated, for the evil itself continues to grow with the increase of population, until the earth or subsoil of the city is so thoroughly permeated with human excreta as to render its removal an absolute necessity; to accomplish which end, capital and industry, under the direction of the civil engineer, have constructed systems of sewers, through which, with the water from public water-supplies and rains as vehicles, the refuse, etc., from dense populations is carried to running streams and rivers, to be diluted to an extent which makes it harmless. Hence a system of thorough drainage, through the medium of sewers, is next in importance to a public water-supply for a city as a means of preserving the health of its inhabitants. This is a subject upon the investigation, development, and perfection of which the ablest statesmen, scientists, and engineers of great Britain and the continent of Europe have been engaged for years; and in the United States, also, much attention has been given to the subject, although the literature or written experience in relation to it is quite meagre. In a late publication* upon this subject the author truthfully remarks: "The general standard of public morals always corresponds with the state of public health, the latter depending again upon abundance of food combined with a pure atmosphere and an unlimited supply of undefiled water. * * *

In nothing is the superior wisdom of the present Emperor of the French so manifest as in the undivided attention he,

* Kropp's London Sewerage.

like the founder of his dynasty, pays to the sanitary, agricultural, industrial, and commercial interests of his people, which thus manifestly proves that true statesmanship finds its best allies in agriculture and public health."

The tables 1 and 2 give respectively, the quantity of water consumed, and the cost and other mechanical features of water-works in various cities. Table 3 gives the particulars of the principal artesian wells. Table 5 gives the duty of several of the best engines in the country, and is taken from the report of Jas. P. Kirkwood, C. E., on the Brooklyn water-works.

THE ARTESIAN WELL, sending forth a constant stream of pure water, is a beautiful and interesting sight; and in the popular mind it is invested with a great degree of novelty. What is an artesian well? Historically, it is so called from a mode practised in Artois, a province in France, by boring for water. Technically, an artesian well is a mode for obtaining a spontaneous flow of water, at or above the surface of the earth, through the medium of a tubed perforation of the earth's crust, extending in depth until a body of water is reached, from which, by hydrostatic pressure, a portion is delivered through the tube at or above the surface of the earth. The most plausible theory, explanatory of the flow of water

* Approximate.

from artesian wells, is their similarity to natural springs, there being in both contracted apertures from the surface of the earth to the subterranean reservoirs full of water, and compressed by columns of this liquid. Through these apertures (natural fissures in the earth in the case of springs, and artificial borings in the case of artesian wells) the water escapes, seeking its level. The history of artesian wells, so far as they have been resorted to as a means of supplying towns and cities with water, is not at all encouraging, whatever may be their merits as means of obtaining limited quantities of water for private or special uses.

The following extracts are from a report by V. Dumas, member of the French Academy of Sciences, to the Minister of Public Works, on the subject of the exclusive water-supply of Paris by artesian wells:—

"The commission is unanimous (against the scheme). Among its members there are none who are unaware of the importance of artesian water drawn from the green sand for the use of Paris. But among those who base upon it the greatest expectations, there are none who are of opinion that it would be advisable to exclude the employment of other resources that nature or art has placed at the disposal of the Parisian people. * *

"1. The water-bearing stratum of green sand is not the exclusive property of the city of Paris. It can be operated upon at any distance or level by the proprietors of the soil. The works constructed by companies, associations, and individuals, however great or indisputable may be the capabilities of this source, could absorb them and render them of very doubtful application to the municipal wants.

"2. The phenomena and natural accidents, such as earthquakes, that exercise little influence upon canals through which flows surface water, could, on the contrary, produce on channels for the passage of water at great depths a derangement of their course.

"Though such events may be rare, it is sufficient to know that once in twenty years their effect on the well of Grenelle has been observed, not to be willing to expose the city of Paris to receive suddenly and for entire months turbid water in all its reservoirs, or to submit to a diminution of one-half the product of its flowing wells, which, though it were but temporary, would not be the less serious.

"3. The art of boring is not yet advanced enough by experience in tubing very deep wells of large diameter, especially in what concerns the green sand basin ; tubes in iron do not last ; copper tubes even, lined with tin, might fill the people with anxiety in times of epidemic; wooden tubes are uncertain; and wells not provided with tubes have not been thoroughly experimented with.

"4. The water of the artesian source, which is of great purity, and which, so far as mineral substances are concerned, is better suited than all others for industrial and public use, is very slightly aerated and tepid. It would be necessary, therefore, to cool and aerate it, to render it useful for domestic purposes ; and for this reason it would be regretted that it is not a little richer in carbonic acid and carbonate of lime.

In conclusion, when we talk of supplying 2,000,000 inhabitants, it is prudent to assure ourselves of the simultaneous use of bodies of water taken from various sources, in order to be always ready to quiet the complaints of the people. Water, as we have said, ought never to be suspected ; and, in case of the least doubt, the administration must be able to replace one water, though suspected without cause, by another which may possess the confidence of the consumers.

The Memphis Works.—The plans proposed for the supply of Memphis are :—

1. A supply from Wolf river, taken at the most available point above the town of Raleigh.

2. A supply from the Mississippi river, drawn at the first suitable point above the city.

3. A supply from the Mississippi river, taken in the vicinity of Hatchie Lake.

The Pumping Machinery recommended in the report for the Wolf River Works, is the Worthington Duplex Pumping Engine. The report says:—

This machine is strictly a steam pump, consisting of two steam cylinders and two water cylinders laid horizontally in pairs, the piston rod of each steam cylinder extending to its water cylinder and working a water-displacement plunger; the steam and water cylinders being separated a sufficient distance to permit the requisite mechanical devices to be attached to each connecting rod between the steam piston and the water plunger, for working the steam valves and air-pumps; the connecting rod of the right-hand engine working the steam valves and air-pump of the left-hand engine, and *vice versa.*

The machine is self-contained, and does not require expensive masonry foundations; it works horizontally; has the smallest mass of inert matter in the moving parts, being just sufficient for the safe transmission of the power; and thus, in conjunction with its moderate velocity, reduces its liability to accidents to a minimum. The valves are multiform vulcanized rubber disks, strengthened by perforated cast-iron disks, the rubber seating upon grated composition-metal valve seats; the receiving and delivery valves are disposed in sets vertically one above the other, and rise and fall vertically.

In the economical use of fuel this engine compares favorably with the best pumping-engines in the country; and in its daily performance it will give moderately good results, with perhaps less attention from skilful enginemen than any other kind of pumping-engine now in use, being nearly automatic in its operation. It has been in use for a number of years, and there are at present in successful operation as follows, to wit: 1 pair at Harrisburg, Pennsylvania; 1 pair at Greenwood Cemetery, Long Island; 2 pairs at Cambridge, Massachusetts; 2 pairs at Charlestown, Massachusetts; 1 pair now being erected at Salem, Massachusetts; and 1 pair at Newark, New Jersey; the last 4 named being each capable of elevating 5,000,000 gallons water per 24 hours.

Wherever this pumping-engine has been in use, it has given entire satisfaction, and, with the exception of the Cornish pumping-engine, it has been duplicated a greater number of times than any other engine for water-work purposes, despite its recent origin.

PREVENTION OF SCALE IN BOILERS.

Translated from Dingler's Polytechnic Journal, by John B. Pearse.

In a late meeting of the Society of German Engineers for the Westphalian District, this subject was proposed for discussion. The remarks were opened by Dr. List, who divided all the means for its prevention into two classes : 1st, those consisting in the addition of various substances to the feed water; 2d, those consisting in the use of special apparatus. The former class of means includes among many others the use of starch or substances containing it, which shall cause the precipitation of the solid matter as powder or mud and not as scale. The results obtained by the use of starch were unfavorable according to the experience of a member. Dr. List mentioned the use of a soft greasy variety of clay, more or less mixed with bituminous matter (Halloysite). Mining Inspector Schrader stated that such clay had been advantageously used at several coal mines with which he was acquainted. Dr. List supposed that the particles of solid matter on being precipitated were taken up by or clung to the clay, instead of adhering to the bottom and sides of the boiler.

Dr. List also mentioned the use of various substances containing tannin. Their utility might be explained both on mechanical and chemical grounds. He had himself obtained favorable results from their use in water containing lime. In sugar factories the addition of crude molasses to the water had had a good effect.

As far as the chemical action is concerned, the utility of such additions depends on the composition of the water. If the latter contains gypsum or sulphate of lime, scale is formed, because the relative quantity of gypsum increases as the water is evaporated, and because the solubility of the same decreases with the heat of the water. If the water contains double or bicarbonate of lime, this compound is decomposed by the heat, and the simple carbonate is precipitated as scale.

The *gradual* separation of these substances causes the formation of scale. Chemical means may prevent such separation, or may hasten it so much that mud is formed instead of scale.

Sal-ammoniac is recommended for preventing the precipitation of lime by forming the readily soluble chloride of calcium. This means is frequently used, particularly in Holland, for locomotives. The most natural means, however, for water containing bicarbonate of lime, would be to hasten the precipitation by the use of a solution of slaked lime in water, or "lime water." This would separate all the bicarbonate of lime as an insoluble mud. Chloride of barium would be the best addition to waters containing sulphate of lime, or those from many coal mines, and would act in a similar way.

Carbonate of soda is recommended from actual experience as an effectual means of preventing scale from water containing either carbonate or sulphate of lime.

M. Helmholy remarked that he had

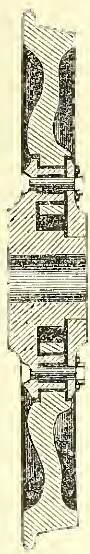
observed incrustations in Giffard's Injector, where the motion of the water was quite rapid. M. Weistman had also observed scale at point, where the velocity of the water was considerable, but mentioned the absence of scale in the boilers of steam fire engines. M. Kamp had also observed the deposition of scale in feed water pipes, although the deposition in the boiler was inconsiderable.

The translator has observed a case where it was attempted to blow charcoal through tubes by means of air, possessing considerable velocity. It was found that although the wind would take along with it some considerable quantity of charcoal, it would nevertheless deposit a good deal again, before reaching its destination, particularly at places where there were angles, or the pipes expanded slightly. The deposition of scale in the injector and feed water tubes might be thus explained without weakening the reasoning of Dr. List, which seems quite correct and conformable to experience.

ELASTIC RAILWAY WHEELS.

Over 10 years ago, that veteran Locomotive Superintendent, Mr. George S. Griggs of Boston, commenced using blocks of wood an inch thick, forming an almost continuous tyre, between the iron tyre and the cast-iron driving wheel rim of his locomotives. The results have been well defined and entirely good and economical, and they have certainly not been arrived at without due trial. The wear of tyres and the breakage of wheels and connected parts has been decidedly lessened by the interposition of this elastic medium, slight as is its yielding; and if of tyres, then of rails and permanent way, for although there may be 30 or 40 times as many truck wheels as drivers in a train, the drivers are 5-ton hammers, while the truck wheels are only little 2-ton smithshop hammers, that would not be employed by knowing smiths if the lamination of rails was the thing to be aimed at. Every body concerned has known all about Mr. Griggs' wheel for years, but it is only just now getting into general use.

Mr. W. Bridges Adams, of London, another veteran engineer, long since devised the "horse-foot" tyre—a steel spring between the tyre and the rim of the wheel, and although it gave good results, it has not yet been largely adopted. The wooden car wheel, with an iron hub and steel tyre, long used abroad, is just beginning to be appreciated here. It is in use on the drawing-room cars of the Hudson River Railway.



Another elastic wheel, for cars and other vehicles, a section of which is shown in the engraving, has been devised by Mr. John Raddin, of Lynn, Mass. The hub, and the web and tread are separate castings, between which there is interposed a ring of india-rubber. The holes in the web to receive the projections on the hub, are larger than the projections, so as to give a slight play—say one-eighth of an inch maximum. The rubber being compressed tightly in the annular space, cannot be squeezed out, but can only change its figure when the load comes upon it. The entire *jar* of the wheels is thus absorbed by the rubber before it reaches the hub and the axle. That both the running gear and the permanent way will be made safer and more durable by this elastic relief, is perfectly well assured by similar results in railway and other engineering practice. The economy of having the wheel in two parts, so that the tread may be renewed without forcing the hub from the axle, is obvious. The theoretical advantages of an elastic wheel will not be questioned by intelligent practitioners. Are there any practical defects or weaknesses in this method of application? The management of the Eastern Railroad say that after running 8 of these wheels for 9 months under a 22-ton iron car, an examination showed the rubber uninjured and the nuts all tight, though the bolts were not headed. The same wheels since placed under a passenger car, have run, in all, 40,000 miles with decidedly less wear on the tread than solid wheels. The Engineer of the Boston Fire Department gives an equally good account of similarly cushioned fire-engine wheels.

The use of elastic media between parts subjected to jarring, is now so well understood by railway managers, that we expect to see other and better applications.

Here is a large field for experiment and invention. Although the uniform elasticity of permanent way should be much better provided for than it is, the cost of a pair of well-appointed cushions upon each of a hundred million railway sleepers, looks rather formidable. The proper cushioning of a thousandth part of that number of the heaviest-loaded wheels of engines and trains, is more likely to be accomplished, and would do more good in proportion to the cost.

BRITISH RIFLED ARTILLERY.

Rifled guns had been experimented upon in England for about half a century before they were put to any practical test, but when the Russian war was imminent, it became necessary to adopt some form of rifled artillery, in order to oppose the rifled small-arms which began to be generally adopted. Metallurgy and mechanics had been improved in consequence of the stimulus given to these sciences by the great demand for efforts of civil engineering, and without these improvements the manufacture of rifled ordnance would have been impossible. When the war with Russia broke out, some 8-inch and 68-pounder iron guns were bored on Lancaster's system, and sent to the Crimea and to the Baltic, but they were of small avail, as the straight-sided projectile often jammed in their spiral bores.

It was in the Italian campaign of 1859 that rifled artillery was first used with any effect. The Emperor of the French, with his muzzle-loading bronze rifled field guns, did great execution, especially at Solferino, and scattered terror in the Austrian ranks more by the range than the accuracy of their fire. This success induced all European Powers to turn their attention to rifled artillery. Austria adopted the French system, while Russia and Prussia became converts to a breech-loading action invented by Mr. Krupp. England turned her attention to a breech-loading system invented by Mr. Armstrong, of Elswick. His guns were tested by the rough usage of war in China in 1860, and acquitted themselves admirably. It was known then that the Armstrong guns were excellent, and exceeded in range and accuracy those of any Continental Power. It was vainly thought that this system would have been permanently adopted into the service, at least for field artillery. The same system of ordnance did good service in New Zealand in 1864, but, though no enemies could stand against it in the field, it had potent antagonists at home.

In 1863, under the pressure of polemical writings, the Secretary of State for War appointed a committee to examine and report upon the different descriptions of guns and ammunition brought forward by Sir W. Armstrong and Mr. Whitworth. This committee sat for two years, and conducted a series of experiments, which cost £35,000 in stores alone. The total expenses cannot have amounted to much less than £60,000, and the result was that the experiments were very creditable to both inventors. The contest was very close; and surely no country but England, when it had a gun better than that of any Continental nation, would have spent £60,000 in investigating the infinitesimal differences between it and the offspring of some rival inventor. Still we did so; and the committee which was called on to decide this question thought that muzzle-loading guns, which had been already six years in the French service, were superior to breech-loaders for the service of field artillery. This opinion necessitated another committee to decide on the rival merits of muzzle-loading or breech-loading field artillery. In 1866 another committee assembled to discuss this question, and decided that muzzle-loaders were better adapted for field service than breech-loaders. The consequence was, that a muzzle-loading gun slightly different from the French gun was considered the proper gun for our field artillery, on account of its simplicity. We had thus spent at least 7 years and lost vast sums of money in determining theoretically that a gun which had been adopted at the outset by the French was better than our own, which had been proved to be most excellent on two separate occasions in active service. Yet when we had obtained this decision we could not act upon it, as we dare not incur the expense of arming all our field batteries afresh with muzzle-loading guns. This is the plain result to which we have attained in field artillery; of heavy guns we propose to speak at a future time. The money which has been squandered in experiments cannot be recovered; it is hopelessly lost; and, of course, in a short time, in consequence of the decision of the last committees, unless, indeed, they are subverted by those of some future bodies, our breech-loading field artillery will be supplanted by muzzle-loaders.

Yet is there much reason that this expense should be incurred? It would, perhaps, have been better to have adopted a muzzle-loading gun in the first instance; but, now that we have a breech-loader, is it worth our while to incur all the expense and inconvenience of changing our armaments in order to gratify the whims of theorists or the fancies of mathematicians? The breech-loading gun has been found to do good service in China and New Zealand, and is undoubtedly far above the average as a gun. In the late German war the breech-loading gun triumphed over the muzzle-loader, and the victorious Prussians have adopted it it universally into their service. Impartial and experienced judges, who saw it in action, have told us that the breech-loading gun of the British artillery proved itself superior in China to the Prussian gun in Bohemia. It is, no doubt, superior to the Austrian muzzle-loader, which is very similar to the French gun. Why should we, then, incur a great deal of expenditure to change our armament, when we can already more than hold our own against that of any other nation? Metaphysicians and fanciful artillerists may aim at perfection, but we cannot afford to adopt every momentary invention which professes a very small advantage over the system already adopted into the service. We might, possibly, if we were to reconstitute our whole system, institute muzzle-loaders, and so reap all the fruits of our experience; but now that we have a gun in the service which is considerably better than any possible antagonist, we must deprecate the expense necessary to change for any fanciful advantage. We must remember that, ere the muzzle-loader can be made our armament, some new invention which will nullify it may be brought forward, and, happy in the goodness of our bad bargain, we may be quite content to let well alone.—*Army and Navy Gazette.*

LOCOMOTIVES OF THE NORTH LONDON RAILWAY.—The standard engines of this line are fully illustrated in the "Engineer," Dec. 11 and 25. They have 2 pairs of connected drivers 5 feet 3 inches diameter, and 8 feet apart centres. The truck has 4 wheels, 2 feet 8 inches diameter and 5 feet 8 inches apart. The centre of truck is 9 feet 10 inches from the centre of forward driving shaft. The boiler shell is 4 feet 1 inch inside diameter by 10 feet $2\frac{1}{2}$ inches long, and contains 122 tubes 2 inches diameter. The fire-box is 4 feet $5\frac{1}{2}$ inches long by 3 feet $7\frac{1}{4}$ inches wide by 5 feet 4 inches high inside. The cylinders, outside, and inclined 1 in 12, are 17 inches diameter by 2 feet stroke. The steam-chests are inside, and the link-motion valve connection is direct. The tanks (1,000 gals.) are at the sides of the foot-plate and in rear of the boiler. The working steam pressure is 160 pounds. The peculiar and strong cylinder fastenings, and the great extent of the rubbing surfaces, are especially referred to. The weight of the engines is as follows;

	Light. tons	Light. cwt.	Full. tons	Full. cwt.	Full. qr.
Bogie, four wheels	15	14	14	14	2
Driving wheels	11	11	14	5	0
Trailing wheels	11	7	14	12	2
Total	38	12	43	12	0

Five of these engines are now completed or in progress; they easily take trains consisting of 30 wagons, each weighing over 5 tons, and containing 10 tons of coal, and 2 heavy brake vans, or about 460 tons in all, up inclines of 1 in 100 in all sorts of weather. Equilibrium slide valves are used on these and all the new engines of this line with great success. The valve has the equivalent of 2 pistons in the back. Two circular flanges project from the back, nearly up to the steam-chest cover. Around these are packing rings which are forced up against the steam-chest cover, with a small pressure due to their area, thus making a tight joint. The area enclosed by the ring is open to the exhaust passage of the valve.

ALUMINIUM BRONZE is used in France for saws and other mechanism requiring great strength and hardness, in place of steel. It has been proposed to cover the steps of the column in the Place Vendome with the same material.

ORDNANCE AND NAVAL NOTES.

Whitworth Gun—Late Experiments. The longest range of cannon shot ever attained, was made by the Whitworth ordnance at Shoeburyness in November last, viz.: 11,300 yards, or nearly 6½ miles. The longest range previously recorded, was obtained in 1861 by Lynall Thomas' 175 lb. shot with a 25 lb. charge, from a 7 in. steel gun at 37½° elevation, viz.: 10,075 yards.

The Whitworth gun referred to, has 9,025 in. (major) and 8.25 in. (minor) hexagonal bore, 140.06 in. long with 1 turn in 117 in. The shells used were cast iron, 31.6 in. long, 8.96 in. major, and 8.18 in. minor diameter, with capacity for 18 lb. bursting charge. The shot were cast iron, 24.5 in. long. The wads were hexagonal; weighing 1 lb. each and made of paper maché. Large grained rifle powder was used. The result of the firing was as follows:

No. of Shot.	Weight of Projectile, lbs.	Weight of Charge, lbs.	Elevation.	Range, yards.	Time of Flight.	Deflection, yards.
1	310	50	10°	4,868	13.5 sec.	1 L
2	250	50	10°	5,196	14.2 sec.	7 R
3	310	50	10°	4,021	12.1 sec.	6.2 R
4	250	50	33°	11,300		
5	250	50	33°	11,234		
6	310	50	33°	11,075		
7	310	50	33.5°	11,127		

New British Gun.—An order has been issued from the War-office announcing the introduction into the service of a new description of wrought iron muzzle-loading 10 in. 18-ton gun, of which the following is the official technical description:—Length of gun, 14 ft. 2 in.; mean weight of gun. 18 tons 24 lb.; mean preponderance, 8 cwt. 1 qr. 24 lb.; length of bore, 145.5 in.; length of rifling, 118 in.; calibre, 10 in. The "A" tube is to be made of tough steel. This new description of ordnance is of the general type represented by the 7, 8, and 9 in. guns. They are rifled upon the Woolwich system with seven grooves, having a twist increasing from one turn in 100 calibres at the breech to one turn in 40 calibres at the muzzle.

The vent enters the bore at 11 in. from the end, and upon the right-hand side, at an angle of 45 deg. to the vertical axis on the transverse section, and directed to the axis of the gun. The vent consists of a steel bush, lined with copper, screwed in from the exterior against a platinum tip screwed up from the interior. This tip has a flange, or button-shaped head, projecting into the bore, as a means of preventing the gas escaping into the joint. A projecting head is left upon the bush to enable it to be removed when required by a spanner. The bottom of the vent is enlarged to a diameter of .32 in., tapering up to .222 in. (the diameter of the vent channel) in a length of one inch. The guns are sighted in the ordinary manner at a deflectional angle of 1 deg. 10 min., but this angle is only to be regarded as provisional. They are fitted with "plates, metal, elevating," and "pivots." The cascable faces are graduated for the Engineer of the road tangent scale use.

Use of Railways in War.—The movements by railroad of the Ninth corps under General Burnside, from Central Kentucky to Vicksburg; the transfer of the Twelfth and Thirteenth corps, under Hooker, from Washington to Chattanooga; of the Twenty-third corps from Eastport, on the Tennessee, to Washington, are remarkable instances of the usefulness of this new military arm. The last-named marvellous feat, Mr. Stanton declared to be "without parallel in military history." The distance travelled was 1,400 miles, the troops moved were 20,000 strong, besides 1,000 animals and a full artillery train. It was accomplished in mid-winter, with rivers and roads blocked by ice, in an average time of 11 days for each subdivision.

The campaign of 1866 in Germany demonstrated the importance of the part which railways are called on to play in modern strategy. The Federal Council of Northern Germany has had under consideration a proposition for the drawing up of a complete table of the resources and military advantages of the lines included in the Confederation. With this view a statement is to be compiled every two years, commencing with 1870, in accordance with an official formula, showing the capabilities, in a military point of view, of the existing railways and the branches to be constructed. An interesting work has been written on the subject in German. The Italians are busy organizing a system for turning their lines to the best use, and here engine-drivers and stokers are attached to every regiment.

Use of Breech-loaders Abroad.—In the North German army the infantry of the line and the guard are all armed with needle-guns, of which there is also a sufficient supply for the reserve and for the garrisons. The arming of the whole of the landwehr with converted needle-guns was also decided upon last June. Of the South German troops, those of Hesse, Baden, and Wurtemburg are all armed with the needle-gun, while Bavaria only began a few months ago to supply the Werner gun to her army. Austria had armed 300,000 men with the converted Wanzl last July. The whole of the French army may be regarded as being supplied with the Chassepot since last spring. In Belgium the Albini gun was to be in the hands of every soldier of the line by the 1st of October. In Italy 32 battalions of bersaglieri were armed last July with a rifle similar to the Prussian needle-gun, with slight modifications. The English army has, since the beginning of the year, carried the Snider. The arming of the Danish army with the Remington rifle is also complete; and Russia makes the greatest efforts to hasten the supply to her troops of Carlen needle-guns. Of the other States, Holland, Sweden, Roumania, and Servia have only just introduced breech-loaders into their respective armies, while in Turkey, Spain, and Portugal the soldiers still carry the old musket.—*Cologne Gazette.*

U. S. Ordnance Report.—The expenditures of the Ordnance Department during the last fiscal year, for all purposes, inclusive of the payment of war claims, were a little more than three millions—less than three-fifths of the expenditure of the preceding year.

There are 27 military arsenals in all, including the National Armory at Springfield. The work done at them by the hired mechanics and enlisted men of the Ordnance Corps, under the direction of skilled officers of the corps, has been economically and satisfactorily performed.

Highly favorable reports of the breech-loading converted Springfield musket have been received from those portions of the army where it has been distributed.

A few smooth-bore and rifle guns, of heavy calibre, are being made, for trial of their power and endurance. When the most suitable kinds have been determined, a large number of guns for fortifications will have to be made, and authority to make them as fast as can be done is asked.

Torpedoes.—Further experiments have been made at Toulon with torpedoes, and it has been decided that in case of war, that port shall be strongly defended with these submarine monsters. The Government, however, thinks that the torpedo subject is one which should be confided to a special corps, and hence a school is to be established at the Isle of Aix, where the mysteries of those engines of destruction will be taught.—*Army and Navy Gazette.*

United States and British Squadrons.—At the date of the report of the Secretary of the Navy, we had on duty with our various squadrons, 38 vessels, including storeships, mounting in all 347 guns. On December 5th, the English had, within the limits of their several stations, 116 vessels, mounting in all 1,146 guns. From this it would appear that, besides their Channel fleet, the English have three cruising vessels in squadron service to our one.

New English Monitor.—The "Cerberus," recently launched at Jarrow, and designed by Mr. Reed, is 225 feet long by 45 feet 2 in. beam, and 18½ feet deep, the draft being 15½ feet. There are 2 turrets, 21¼ feet diameter. The turrets stand on central spindles and are revolved by auxiliary engines. Each turret carries two 18 ton 450 pdr. Armstrongs. The hull is divided into 7 water-tight compartments. The vessel is to go to Australia.

The Chronoscope.—A series of experiments carried out at Woolwich with the new chronoscope for measuring the velocity of projectiles within the bore of the gun invented by Captain A. Noble, late of the Royal Artillery, have been attended, it is said, with great success. The instrument has proved itself capable of measuring the hundred-thousandth part of a second with great accuracy.

Ordnance Experiments.—It is stated that Admiral Dahlgren, Chief of the Naval Bureau of Ordnance, will ask Congress for a limited appropriation to be used in experimental gunnery, as no appropriation has been made for this purpose for the Navy.

Krupp vs. Armstrong.—The German papers claim a decided victory for Krupp over Armstrong in the late trials of the rival systems. The English gun was shown to be inferior and split at the 264th round, while the German gun was fired 400 times without being damaged.

IRON AND STEEL NOTES.

Use of Manganese in Steel Making.—Mr. Robert Mushet, in replying to a paper on iron and steel by Messrs. Hinde, says:

In their remarks on the effect of spiegeleisen, and of the preparations of manganese with carbonaceous matters, as set forth in Vickers' and Heath's patents, Messrs. Hinde have gone completely astray, and have fallen into the common error of supposing that spiegeleisen is added to oxygenated iron solely to recarbonize such iron. The fallacy of this opinion has been clearly shown where ferro-manganese in place of spiegeleisen has been used to de-oxygenate molten Bessemer metal, the results obtained being far better than when spiegeleisen is employed. Now, ferro-manganese contains only about one-fifth as much carbon as spiegeleisen, and nearly four times as much manganese, and were it possible to produce pure metallic manganese free from carbon, at a cheap rate, it would wholly supersede spiegeleisen, and would enable manufacturers of Bessemer metal to obtain from inferior numbers of hematite pig metal, steel of as good a quality as they now obtain from best selected pigs. Nothing but metallic manganese requires to be imparted to oxygenated iron to produce steel, and the use of compounds containing other matters, is simply due to the fact that a better or purer form of metallic manganese than is contained in spiegeleisen cannot be economically procured. Neither under Heath's nor under Vickers' process is metallic manganese added to steel. Oxide of manganese is the agent here, and its action is that of a flux. Thus, when blister steel, which, when melted and cast into an ingot, cannot be drawn into a sound bar, or bear a welding heat, is melted with a few ounces of oxide of manganese without any carbonaceous matter being added, and then cast into an ingot, the ingot thus produced can be drawn into a sound bar of steel, which will forge and harden well, and bear a welding heat. In the melting pot, therefore, oxide of manganese, and not metallic manganese, acts as an improver of the steel operated upon. As to either Vickers' or Heath's process being applicable where it is desired to de-oxygenate decarbonized iron, it is a myth.

Park and Love's Steel Process.—This is an invention relating to the manufacture of cast-steel, and the furnaces used for that purpose, and also for remelting. The furnace consists of two fire chambers, separated by a fire bridge; one of these chambers receives a crucible, and the other contains a reverberatory fire chamber. Both chambers are in connection with the crucible, which is surrounded with fuel. The second chamber has a curved or arched top, to direct the flame into the crucible chamber to the fuel therein, or to the open mouth. The crucible is provided with discharge holes. After bringing both fires to a white heat, molten cast iron is poured into the crucible in such quantities as will form steel, together with malleable iron. Vitreous fluxes are introduced. Wrought-iron scraps, previously brought to a white heat in an adjoining furnace, are introduced into the cast-iron in the crucible. When the cast and wrought irons are mixed and melted together, the contents of the crucible are drawn off through the discharge holes. Puddling may be carried on in the furnace by making the working hole at the top instead of at the side. The puddling instrument is an iron ball on a bar, worked up and down by chain and pulley, or by hand.

James and Jones' Steel Process.—Messrs. James (of Ebbw Vale) and Jones (of Govilan) have specified a patent relating to the manufacture of steel, under which they claim the application of carbonizing and nitrogenizing gases under pressure to wrought iron in a receiver closed gas-tight. These gases are formed in a separate generator, and thence forced into the receiver through an accumulator or otherwise, or the gases may be formed in the receiver itself, partially or wholly. The nitrogenous gaseous compound preferred is cyanogen gas. They also claim the use under compression of blast-furnace waste gases, containing carbonic oxide, ammonia, and nitrogen; also other waste gases containing the necessary elements for the conversion of wrought iron into semi-steel or steel.

The Siemens-Martin Process.—Messrs. B. Samuelson & Co., of Middlesborough, write to "Engineering" that they do not (as had been stated) remelt the ingots produced by this process, but roll them, without hammering, into soft steel plates, capable of resisting a tensile strain of from 34 to 35 tons per square inch, and into rails which have withstood repeated blows of a weight of 21 cwt., falling from a height of 26 feet. As to the use of Cleveland iron—whilst it has not been possible to use it for the bath, they have, by Richardson, Johnson & Co.'s process of purification, succeeded in freeing the puddled bar, made out of Cleveland iron, from phosphorus to a sufficient extent to obtain the results stated.

The Temperatures (centigrade) best adapted to the tempering of various instruments are seen in the following table:

Lancets	210°—215°
Other surgical instruments	220
Razors	225
Penknives, erasers	230 —235
Scalpels, cold chisels for iron	240
Shears, sheep shears, gardening tools	250
Hatchets, axes, plane irons, pocket-knives	260 —265
Table knives, large scissors	270 —275
Swords, watch springs	285
Large springs, daggers, augers	290
Saws, some springs	310 —315
Various other instruments requiring less hardening	320

Chromium Steel.—It has long been known that an alloy of 60 parts of chromium and 40 parts of iron is so hard as to scratch glass like a diamond, and such an alloy may be formed by heating oxide of chromium in a blast-furnace with metallic iron. Experiments are now being carried on to produce a species of steel, suitable for rails and other purposes, by adding chrome ore and manganese to the iron in the puddling furnace; and the results are said to be promising, though not yet conclusive.

Creusot.—The Bessemer process is being introduced on a vast scale, and 80 new puddling furnaces are being added to this immense establishment.

Powder Hammer.—If the following, which has "gone the rounds," etc., for a year or so, *works*, a description of the apparatus, mould stoppers, strength of parts, etc., it will be gladly and prominently quoted and credited by Van Nostrand's Magazine: A French periodical states that Mr. Galy Cazalat has invented an ingenious process for compressing molten steel, intended for guns, so effectually as to save all the labor of hammering. In the upper part of the mould into which the metal is run is an apparatus containing a small quantity of highly inflammable powder, which, in burning, generates gas in such quantity as to produce thereby, in a short time, a pressure of ten atmospheres. This pressure expels the gases contained in the steel, and forces the metallic molecules into the closest union.

Iron or Steel Direct from the Ore.—In order to produce iron or steel direct from the ore, Mr. G. W. Nasarow, of St. Petersburgh, treats the ore with a solution of carbonate of soda in water, allowing the solution to stand a considerable time in contact with the ore. The weight of the carbonate of soda employed may be about one-fortieth part of the weight of the ore. The ore thus prepared is placed in a furnace—a reverberatory furnace supplied with a hot blast may be advantageously employed. The ore is melted down and iron or steel is obtained, according as the metal is allowed to remain in the furnace a longer or shorter time. The compact bloom obtained may be forged and rolled. Scrap iron may be treated in the same way, but in some cases it is necessary to add more carbon.

Iron from Pyrites.—Experiments are now being made in New York, with a view to the production of merchantable iron from pyrites. At a recent meeting of the Lyceum of Natural History, Professor Eggleston stated that the furnace employed is similar to an old Swedish furnace, very much cut away, and steam heat is employed; the material is kept in the lower part of furnace at a white heat, till agglutination takes place; the pasty mass is then skilfully worked and separated into grains, and afterwards withdrawn. He would not prejudge the case, but entertained no hopes of success.

Manufacture of Steel.—Puddled bar is converted into steel, according to the invention of Mr. V. Gallet (referred to in the *Mining Journal*), by coating the bars with a paste composed of wood charcoal, 20 parts; soot, 12; lamp-black, 15; ivory black, anthracite, plumbago, 1 each; carbonate of lime, 33; carbonate of potash, 3 to 20 parts; carbonate of soda, 10; caustic potash, sea salt, sal ammoniac, 1 each; clay, 13; oxide of manganese, 3; and resin, 3 parts—the whole combined with water. The iron is coated with the paste, and the cementation conducted in the usual manner.

Shotting Melted Metal, by pouring it into water, is largely practised, and is a very convenient way of reducing iron and steel for remelting. But if the mass of water is not very great compared with the mass of metal, and if it is not kept cool, the generation of steam will cause explosions. In several of the Bessemer steel works, where shotting steel for remelting in crucibles is practised, explosions of various intensity have occurred—some simply throwing up the water and bursting the tank. In Silesia, recently, a shotting tank burst, killing and wounding several men.

Cost of Bessemer Plant.—Much is being said, just now, in connection with new modes of making steel, of the great cost of the Bessemer plant. Yet a plant capable of turning out upwards of 12,000 tons yearly, or 250 tons weekly, viz., a pair of 5-ton converters, with all machinery complete, costs but £6,000; the interest upon which, together with fuel, attendance, repairs, and depreciation, would hardly amount to half-a-crown a ton, whereas the cost of ingot moulds alone, necessary in all steel melting, by whatever process ingots are made, is as much as 4s. per ton. Of the Bessemer plant the cost of a double-blowing engine, with a pair of 3 feet steam cylinders and 4½ feet blowing cylinders, with a stroke of 5 feet, is £1,800, or, with boilers, less than £2,500. As compared with the cost of machinery necessary to work the product of such a plant, its own cost is very little indeed. For, with £6,000 outlay for Bessemer plant, £80,000 or so would be expended in the hammers, rolls, engines, boilers, and miscellaneous machinery, requisite for working up 1,000 tons of ingots monthly into goods.—*Engineering.*

The Pennsylvania Steel Works.—It is now over a year since a charge of steel has been lost at these works through any failure of the machinery, tuyeres, vessel-bottoms, or refractory materials. To those familiar with the English practice, this will appear a remarkable result. It is due, of course, to good construction and careful management. The American refractory materials, as far as developed, are not equal to the English.

New Auxiliary to the Bessemer Process.—John Francis Bennett, of Pittsburgh, has patented the use of carbonic acid gas, either alone or mixed with atmospheric air, or with other gases or vapors, when introduced into molten iron or other metal for the purpose of removing sulphur, phosphorus, and any other impurities which will form combinations with the oxygen of the carbonic acid, and deposit the carbon. It is said that this process is about to be tried at the works of John Brown & Co., Sheffield.

Costly Steel-Making.—An invention explained at a recent Converzatione of the Institution of Civil Engineers, consists in grinding pig-iron to powder by a very rapidly revolving cutter. The great heat generated sets the particles of metal on fire, and after scintillating, they fall down in a reddish brown dust, which is gathered, placed in a crucible, and melted.

The Bethlehem Iron Co. have purchased the Northampton (new) furnace near their works, and are adding a foundry and a new rolling-mill, with Siemens furnaces, to their already extensive plant, viz.: 2 blast furnaces, a rail mill, producing 90 tons daily, and a very large machine shop.

The French Railway and Naval Blast Furnaces, Forges, and Steel Works Company have introduced the Bessemer process for the manufacture of steel in their Givors Works.

RAILWAY NOTES.

Railways in the United States.—The development of our railway system has been more rapid during 1868 than ever before. We have a nominal increase of 3,450 miles of road, costing $193,245,232. The actual figures are probably 3,000 miles at $150,000,000 cost. The following table shows the distribution of mileage and cost:—

	Miles of Road.		Cost of Road and Equipment.
	Total.	Open.	
Maine	944.19	559.67	$19,789,521
New Hampshire	783.72	668.72	21,975,319
Vermont	643.59	603.59	24,347,149
Massachusetts	1,537.36	1,4[illegible]5.43	68,345,521
Rhode Island	121.47	121.47	5,006.665
Connecticut	782.66	641.23	23,064,859
New York	4,459.58	3,328.87	182,538,123
New Jersey	984 75	972.75	69,770,243
Pennsylvania	4,937.72	4,397.74	256,772,257
Delaware and E. Maryland	362.90	242.94	7,483,596
Maryland (other than above)	654.95	457.45	28,520,899
West Virginia	605.85	364.75	22,404,100
Virginia	1,909.88	1,464.27	47,549,038
North Carolina	1.617.79	1,096.67	25,687,414
South Carolina	1,338.17	1,076.17	25.131,600

Total Jan. 1, 1869	62,917.10	42,272 18	$1,853,706,041

Street railways, say 2,500 miles, and double tracks and sidings, say 25 to 30 per cent. on the whole, are not included in the above table. The total length of single track in the United States can therefore hardly fall short of 60,000 miles. This is the work of 40 years.—*Compiled from the Railroad Journal.*

British Railway Traffic and Maintenance Statistics.—The number of passengers carried in Great Britain in 1866, was 313,699,268, or an average of about 10 journeys by rail yearly for every man, woman, and child in Great Britain. In carrying these passengers 19,228 vehicles were employed, which ran 73,383,356 miles in 3,741,086 trains. It has been computed that to carry such a traffic under the told system would require about 50,000 coaches, and more than half a million of horses.

The number of persons travelling by railway in and out of London averages about 300,000 daily. Nearly 700 trains run over the Metropolitan line alone. The total number of local London trains per day is about 3,600, besides 340 trains which arrive from and depart to distant stations. During the busy hours of railway traffic, morning and evening, as many as 2,000 train stoppages are made hourly for the purpose of taking up and setting down passengers, while about 2 miles of railway are covered by running trains.

The annual loss of iron by tear and wear on the 13,854 miles of railway open for traffic in Great Britain amounts to above 20,000 tons a year, while about 250,000 tons require to be taken up, re-rolled, and relaid. The wooden sleepers, also, perish at the rate of about four millions per annum, to renew which about 10,000 acres of pine forest require to be cut down. To maintain the permanent way, about 81,000 men are constantly employed, at the rate of 5 men per 2 miles of double way. Besides these workmen, there are 13,000 plate-layers employed in laying down and fixing new rails; 40,000 artificers. who construct and repair the rolling stock; 26,000 porters, signalmen, and pointsmen; 6,000 guards and breaksmen; and 11,000 engine-drivers and firemen; or a total of about 177,000 railway workmen.

The heaviest item in the working expenses of railways is that for locomotive power. There were 8,125 locomotives at work in the United Kingdom in 1866, or about 2 engines for every 3 miles of railway open; and the work they performed during the year, was the haulage of 6 millions of trains a distance of 143 millions of miles.

The average working "life" of a locomotive is about 15 years, during which it will run about 300,000 miles, undergoing during that time many repairs and renewals; after which it may be considered used up, when it is sent to the scrap heap. Thus, taking into account the tear and wear of the locomotives at work in the United Kingdom, about 500 engines have to be replaced yearly; and as a good locomotive costs from £2,500 to £3,000, the expenditure on new engines amounts to about million and a quarter sterling yearly.

As to cost of working, a passenger engine will consume about 30 lb. weight of coke per mile, and a goods engine 45 lb. Hence the coal and coke used in 1866 was about two and a half million tons.

The average earnings of each locomotive amount to about £5,000 yearly, or equal to 5s. a train mile. According to a recognized formula, the working expense per train mile is 2s. 3d., which may be thus divided: 1s. for maintenance of stock, 3d. for maintenance of way, 9d. for coaching and goods expenses, and 3d. for miscellaneous expenses.—*The Quarterly Review.*

Fast Running.—A train on the Chicago and Northwestern recently made the unprecedented run of 91 miles in 90 minutes. The quickest prior runs of which we have any record are as follows: In England 18 miles by a special train in 15 minutes. In the United States, 14 miles in 11 minutes, by an engine and 6 cars, on the New York Central; 10 miles in 7¼ minutes, on the Pennsylvania Railroad; 144 miles in 2 hours 49 minutes, on the Hudson River road; 84 miles in 90 minutes, from Indianapolis to Union City; 305 miles in 7 hours 42 minutes, from Albany to Niagara.—*Exchange.*

Oregon Branch of the Pacific Railway.—It will require only about 330 miles of railroad to open a communication between the Union Pacific Railroad, near the north end of Salt Lake, and the city of Portland, in Oregon. The whole distance is 645 miles, but 300 can be travelled by steamboats on the Snake and Columbia rivers.

Permanent Way of the London Metropolitan Railway.—All the rails on this line are of steel, weighing 84 pounds per yard, and resting on sleepers placed about 2 feet 8 inches apart, centre to centre, and 1 foot 10 inches apart at the joints, which are made with fish plates, and 4 bolts seven-eighths inch. diameter. The sleepers are bedded upon 14½ inches screened gravel.

Turkish Railways.—The resources of Asiatic traffic are in a measure shown by the earnings of the Smyrna and Cassaba Railway, 61 miles long, now earning £2,000 a week, or nearly £33 per mile per week. During the week last reported, 4,696 passengers and 2,166 tons of goods were carried.

Railway Ferries are somewhat used in Great Britain. There is one across the Tay at Broughty, and one across the Forth at Granton. They are only for goods trains. The boats carry 25 short cars at a time.

Dutch Railways.—A new link in the line from Amsterdam to Paris was recently opened—the Utrecht and Waardenburg—and the whole line is promised to be completed by the end of this year.

Government and Railways.—A strong pressure is being brought to bear upon the British Government, in favor of buying the Irish railways upon terms submitted during the last session of Parliament by a joint committee.

MISCELLANEOUS.

Resources and Works of Pennsylvania.—The anthracite coal production of this State increased from 365 tons in 1820 to 12,650,671 tons in 1867. The bituminous coal field covers 1,300 square miles; the anthracite, 470. The production of pig iron, begun in 1720 in Chester county, has been increased and diffused until it amounted in 1867 to 839,496 tons. Pennsylvania is first among our States in the production of both coal and iron, and second only to Massachusetts in the range and extent of her manufacturing industry. She has 972 miles of canals, which cost $38,660,397, and 3,097 miles of completed railroads, which cost about $250,000,000, being foremost of all the States except possibly Illinois, in railroads, and before all but New York in canals.

Scale in Locomotive Boilers.—The locomotive superintendent of the Chicago and North-Western Railway, has for 3 years past succeeded, although using very hard water, in keeping his boilers free from scale by merely introducing once in about 3 months, 12 pounds of pure zinc, in pieces about one-half inch square. This appears to gradually clean the boiler, and to prevent the formation of fresh scale. The zinc wholly dissolves in from 3 to 5 months, and the inner surfaces of the boiler plates are then found covered with a thin coating of zinc, as are also the ends of screws taken out for examination.

Broken Screw Shafts.—It is but lately that the Hibernia was lost by the breaking of her screw shaft within the stern tube, the broken ends fouling and so forcing away the after-end of the shaft, thus admitting a flood of water into the hold. The Borussia, of the Hamburg American line, put back recently on her way to New York, with her screw shaft broken, but happily not inside the stern tube.

Strength of Corrugated Iron.—We devote this month more space than we shall ordinarily allow for a single article, to the comprehensive paper on this subject. It is a paper that can hardly be condensed, and as it is comparatively new matter, and likely to be frequently referred to, it will be more useful and convenient in this form, than if divided.

The New York Stock Yard at Communipaw covers, with its buildings, 15 acres of ground. The average market consumption of New York per week is, beeves, 5,500 ; of swine, about 21,000 ; of sheep and lambs, about 22,000. The capacity of this Abbatoir for slaughtering and dressing is : of beeves, from 6,000 to 7,000 ; of swine, upwards of 35,000 ; and of sheep, upwards of 25,000.

New Books.—Under this head we intend to give, each month, the titles of all prominent new books connected with Engineering, together with a very brief abstract of reviews of them by our contemporaries.

The New Dam at Cohoes across the Mohawk river will be the largest work of the kind in the State. It is 1,640 feet long, from 14 to 20 feet high, 16 to 18 feet wide at the bottom, and 10 at the top. Some 500 feet of the dam are completed.

St. Paul's Cathedral.—The total cost of the erection of St. Paul's Cathedral was £747,954 2s. 9d., less than $4,000,000. It is slightly larger than the New York Court House.

Steamship construction and engines will form the subject of a comprehensive article in the March number of this magazine.

The Coffer Dam at Rock Island, is seven-eighths of a mile long, and from 8 to 14 feet wide, and contains a million feet of lumber.

Small Locomotives for mines, quarries, stock yards, etc., to take the place of teams, are building by Grice & Long, Philadelphia.

NEW BOOKS.

Shipbuilding in Iron and Steel. A practical treatise giving full details of construction, processes of manufacture, and building arrangements ; with results of experiments on iron and steel, and on the strength and water tightness of riveted work. By E. J. Reed, C. B., Chief Constructor of the Navy, Vice President of the Institution of Naval Architects, and Honorary Member of the Liverpool Literary and Philosophical Society.

There are several excellent works, by distinguished authors, on this subject. Mr. Scott Russell and Professor Rankine, go very fully into stability and form of least resistance. Mr. Reed treats in a more comprehensive and practical manner of details of construction, and strength of materials and forms. The work is complete in one 8vo volume of 540 pages, and the excellent plan of having the illustrations inserted in the letter-press has been followed, thus avoiding the necessity for a separate volume of plates. There are upwards of 260 wood-cuts, and five steel plate engravings. The book is divided into chapters on the strength of iron ships : on keels, keelsons, and garboard strakes ; on stems ; on stern-posts ; systems of framing, in various chapters ; deck stringers and plating ; bulkheads ; topsides ; rudders ; iron masts ; steel plates for ship-building ; rivets ; testing iron and steel ; Lloyd's and rules for shipbuilding ; armor plating, etc. The best evidence that can be adduced in favor of the practical nature of the work is that the Lords of the Admiralty have directed that the examinations in practical iron shipbuilding of candidates for promotion in the Royal Dockyards will, in the main, be based upon Mr. Reed's treatise.

"Engineering" says of the work :

Not only is it distinguished by its essentially practical tone, and the fullness of the information it affords with respect to details, but it also contains several other novel features, which, in our opinion, are well worth notice. One of these consists in the fact that, instead of giving the usual historical sketch of the progress of iron shipbuilding, that progress is traced in the notices of the various parts of the ship. For example, in the chapter on "keels, keelsons, and garboard strakes," there is given an account of the steps by which shipbuilders passed from the wooden and hollow iron keels and keelsons of the early ships up to the present arrangements. This course is followed throughout the work, and has the further interest of sometimes showing how arrangements which had fallen into disuse had been re-applied recently. Before the appearance of this book, no accurate and detailed account of the changes made in the construction of iron-clads, from the time of the Warrior's building up to the present, had appeared. This want has, however, been supplied most satisfactorily in the present volume. We find in this volume, also, fuller notices of the practice of private builders with respect to the various parts of iron ships than have ever previously appeared. Scarcely any of the great firms remain unrepresented.

Sciography, or Radial Projection of Shadows. By R. Campbell Puckett, Ph. D., Head Master of the Bath School of Art. London : Chapman & Hall, 193 Piccadilly, 1868.

This work is well reviewed by the "Mechanics' Magazine," which says :

Sciography, or the science of shadows, has never received that special attention it deserves. This is evidenced by many architectural drawings, where the attempt to unite the mechanical projection of shadows with perspective representations, produces many errors, and shadows of the most impossible character. To correct this tendency by means of a text-book, has fallen to the lot of Dr. Puckett, who has well performed his part. The work is very properly limited to the perspective projection of shadows, and, therefore, pre-supposes a knowledge of linear perspective on the part of the student. It forms, therefore, a supplement to perspective studies.

The Mechanic's and Student's Guide in the Designing and Construction of General Machine Gearing, as eccentrics, screws, toothed wheels, &c., and the drawing of rectilineal and curved surfaces, with practical rules and details. Edited by Francis Herbert Joynson, author of "The Metals Used in Construction." Edinburgh: William P. Nimmo, 1868.

The "Building News" states that this book goes very fully and satisfactorily into the subject of shafting. The "Mechanics' Magazine" says: The student will find rules for the construction of the above parts of machinery, as well as practical rules and details for drawing rectilineal and curved surfaces. Of course, this work assumes an acquaintance with mechanical drawing. The details and calculations of shafts, pedestals, and pulleys, are carefully considered, after which we have a selection of geometrical problems. The volume is accompanied by eighteen sheets of diagrams.

A Practical Treatise on the Manufacture of Portland Cement. By Henry Reid, C. E. To which is added a Translation of M. A. Lipowitz's work, describing a new method adopted in Germany of manufacturing that cement. By W. F. Reid. London: E. & F. N. Spon, 48 Charing Cross. 1868.

"The Engineer" says this is an excellent and thoroughly practical treatise. The "New York Tribune" says: "Among the chief merits of the book are extensive plagiarisms from Major-General Gillmore's standard American treatise on Limes, Hydraulic Cements, and Mortars. We presume the profession in America are perfectly willing to furnish material for the writers of books on the other side of the water, provided due credit is given, and the ordinary courtesy among gentlemen is observed in the matter."

A Treatise on the Metallurgy of Iron. Containing outlines of the history of Iron Manufacture, methods of assay, and analyses of iron ores, processes of manufacture of iron and steel, etc. By H. Bauerman, F. G. S. First American edition revised and enlarged, with an appendix on the Martin process for making steel, from the report of Abram S. Hewitt, U. S. Commissioner to the Universal Exposition at Paris, 1867. Illustrated with numerous wood engravings. New York: Virtue & Yorston, D. Van Nostrand.

This work has already had a wide circulation, and is officially adopted as a regular book of reference in one of our best engineering schools. For a comparatively small and cheap book, it is perhaps the best and most thorough work in print, on this subject.

Examples of Modern Steam, Gas, and Air Engines. By John Bourne, C. E. London: Longmans, Green, Reader, & Dyer, Paternoster-row.

Parts VI. and VII. of this admirable treatise are now published. The author continues the discussion upon water-jet pumps and pumping engines. He then enters upon the subject of fire-engines. We next have a dissertation upon blowing engines. The plates which accompany parts VI. and VII. represent the slide, expansion and valve gear, and the boilers of R. M. S. "Russia," and the 15 horse power high pressure inverted screw engine, made at the Motala Iron Works, Sweden. The quality of Mr. Bourne's writings on the steam-engine and kindred subjects, is too well known to require comment.

Personal Recollections of English Engineers, and of the Introduction of the Railway System into the United Kingdom. By a Civil Engineer, Author of the "Trinity of Italy." London: Hodder & Stoughton, 27 Paternoster-row, 1868.

In closing a long review of this book the "Builder" says: The book which we have thus condensed will be found amusing, as well as instructive reading. Engineers and contractors will recognize in it many portraits, though the name be not written beneath the picture; and legislators will discover hints here and there deserving their attention. Other authorities do not consider the book as taking rank among scientific works.

Modern Screw Propulsion. By N. P. Burgh. London: E. & F. N. Spon, 48 Charing Cross.

This treatise has reached Part X., in which the chapter on the modern details of screw propellers is concluded, and an interesting chapter on bearings, by Mr. John Penn, is given. Particulars and engravings are given of the experiments and apparatus, by which Mr. Penn proved the practical utility of wood bearings when submerged in salt water. The 3 plates accompanying this part illustrate the geometry of the screw propeller, a 3 bladed twin screw propeller, and the geometry of the Griffith's screw propeller.

Irrigation in Southern Europe, being the report of a Tour of Inspection of the Irrigation Works of France, Spain, and Italy, undertaken in 1867–68 for the Government of India. By Lieutenant C. C. Scott Moncrieff, Royal Engineers Assoc. Inst. C. E. London: E. & F. N. Spon, 48 Charing Cross.

A Practical Treatise on Heat, as applied to the Useful Arts; for the use of Engineers, Architects, &c. By Thomas Box, Author of "Practical Hydraulics." London: E. & F. N. Spon, 48 Charing Cross. 1868.

This is pronounced by competent authorities to be a valuable work.

A Manual of Practical Assaying. By John Mitchell, F. C. S. Third edition, edited by William Crookes, F. R. S., etc. London: Longman, 1868.

This is a new and much enlarged edition of a standard work. It is an octavo volume of 780 pages.

A Practical Treatise on Metallurgy, adapted from the last German edition of Prof. Kerl's Metallurgy. By Wm. Crookes, F. R. S., etc., and Ernst Rohrig, Ph. D., M. E. London: Longmans, 1868.

VAN NOSTRAND'S
ECLECTIC
ENGINEERING MAGAZINE.

No. III.—MARCH, 1869.—Vol. I.

HISTORY OF DECARBURIZING IRON.

The subject of greatest interest, at this time, to the engineering profession, and to the public (excepting only the construction of the new Cabinet), is the cheapening of iron in a malleable form. The success of the Ellershausen process of making malleable* pig-blooms, by mixing ore with iron as it runs from the blast furnace, has stimulated an amount of experimenting entirely unprecedented in the history of the iron manufacture. We venture to say, that in every considerable iron works in the United States, the ore process has been more or less tried, in some form, during the last three months, and that in at least half these establishments the Ellershausen turn-table, or some other mixing apparatus is in process of construction or in experimental use.

Nitrates, for decarburizing crude iron, are also the subject of experiments, either upon the plan of Heaton, or as an auxiliary to puddling. Nearly every expert in iron working has a scheme of his own, and the Patent-office is getting as crowded with iron and steel papers as with claims for velocipedes.

Just at this time, therefore, an abstract of the history of purifying crude iron, will be read, we think, not only with interest, but with profit. Many thousands of dollars that would otherwise be wasted in the attempt to patent processes that are old, may be saved by a careful reference to patents already in existence. The official and most carefully prepared abstracts of specifications, issued by the British Patent-office, may be fairly presumed to embrace nearly every invention of value. Probably no process of sufficient novelty to become the subject of a patent, has remained unprotected, and the British list is likely to embrace the inventions not only of Britain, but of America, France and Germany, because improvements in the iron manufacture are worth more, and will pay better, in England, than in any other country. American inventors generally obtain patents in England first, to be certain of securing their claims there. Of course there are many experiments that never become the subject of patents or publications—but mere experiments that have not been able to lead to successful practice, are no bar to the issue of patents to other and successful experimenters with the same means and in the same direction. And although the publication of the many unrecorded trials and schemes that have been made and suggested would be of interest, it would not be of very great value as compared with a record of patented inventions; there is certainly no means of getting at the unrecorded schemes, except the laborious and costly means of patent suits, which from time to time call up some of the more important ones—generally with little practical effect.

We propose to give abstracts of the "Abridgements of the Specifications relating to the Manufacture of Iron and Steel," in the department of decarburizing and purifying crude iron so as to make it malleable and tenacious. For convenience of reference we shall prefix to each abstract a very brief statement of what the patent is about—the *gist* of the matter; and although

* That is to say, malleable after being sufficiently heated to be got into the form of a puddle ball.

we shall omit all merely formal parts, we shall quote, in the words of the patent itself, all those statements that form the essence of the invention, and would be the subjects of legal claims.

DECARBURIZATION AND PURIFICATION BY MEANS OF CINDER, ASHES, SALT, SILEX, POTASH AND CLAY.

PAYNE, JOHN.—1728, Nov. 21. No. 505.

The improvements in the manufacture of iron consist "in putting certain ingredients into fusion with pig or sow iron; videlicet, the ashes of wood and other vegetables, all kinds of glass and sand-ever, common salt and rock salt, argile, kelp, and pot ash, slegg or cinders from iron furnaces, and forges, proportionable parts of the said ingredients being put into fusion or melted with pig, sow, or other brittle iron, which will make the like change as charcoal does in the fire called the finery in common forges, and will render the same into a state of malleability, as to bear the stroke of the hammer, to draw it into barrs or other forms att the pleasure of the workman, and those or other barrs being heated in the said melted ingredients in a long hott arch or cavern, as hereafter is described; and those or other bars are to pass between two large mettall rowlers (which have proper notches or furrows upon their surfass), by the force of my engine hereafter described or other power, into such shapes and forms as shall be required."

NOTE.—*The "finery" referred to is the run out or fining fire still in use in England—blowing air down upon melted iron to partially decarburize it preparatory to farther refinement. The Bessemer process is a vast enlargement of this idea.*

The "long hott arch" described in another part of the patent, is a reverberatory furnace. This subject and other features of the iron manufacture will be taken up in another series of articles.

Kelp is calcined sea-weed ash. "Argile" or argil is alumina.

FINERY IRON MIXED WITH SLAG, SCALES, SAND, LIME AND OTHER FLUXES, AND SOMETIMES WITH MALLEABLE SCRAP, AND MELTED IN CRUCIBLES.

WOOD, JOHN.—1761, Feb. 5. No. 759.

"A way of making malleable iron from pig or sow metal" and of making "the malleable iron hard or soft or of other required qualities," by "raw pitt coal," some of the operations being "preparatory" and others "peculiarly essential."

The pig iron when prepared as hereinafter mentioned, is put into close vessels of clay and mixed with the fluxes. The crucibles being hermetically sealed, are placed in an air furnace, and their contents are melted; the fluxes and impurities form slag, and "the iron is brought into a tough and malleable state," and then is wrought into bars under the forge hammer. The preparatory operations are,—

1st. "I take pig or sow iron." "This I flourish or heat and work in a common finery, with a blast" and coal fire until it is refined and "brought near to a malleable state," or brought to nature. It is then melted in the close vessels above described.

2d. "To the iron thus flourished I sometimes add a due proportion of small pieces of malleable iron, when the cast metal" is very brittle, and the coals very sulphurous.

3d. "I also take the same cast metal, and melt it down in an air furnace," and then I reduce it "into small grains (according to art) by pouring it into water upon a wheel or roller turned briskly round. The granulated metal" is "mixed with various fluxes, according to its nature and the uses for which the iron is intended, as with iron slag or cinder, scales or scoria of iron, fusible sand and lime, kelp, soaper's waste." The fluxes or additions "I put with the granulated metal into close vessels, and work" in the air furnace, as above described.

4th. The cast iron is sometimes "formed into thin plates," which are broken "into small pieces and put into the pots," with "due proportion of fluxes," and so "reduced to a malleable state."

NOTE.—*Mixing wrought iron scrap with cast iron finds its practical development in the Siemens-Marten process.*

The granulation of iron by means of water and the revolving table, is now practised in preparing iron for crucible steel making and other purposes.

The soaper's waste referred to, is wood ashes containing potash or soda.

The "raw pitt coal" referred to in the title, is used in the finery.

MAKING CAST IRON MALLEABLE WITHOUT BLAST, BY GRANULATING IT AND REPEATEDLY MELTING IT IN POTS WITH CINDER, SCALES, SAND, LIME, ASHES AND OTHER FLUXES, AND SOMETIMES WITH SCULL OR SCRAP IRON.

WOOD, JOHN AND CHARLES.—1763, July 29. No. 794.

The pig iron is either granulated by being poured hot into cold water, or pounded with heavy stampers. Scull or cinder is pounded in like manner. If the iron be of red short quality it is sprinkled with strong lee of kelp, and then flourished or melted in closed pots with proper fluxes, such as slag scales or scoria of iron, sand, lime, kelp, or soaper's waste.

If this operation does not sufficiently flourish or reduce the iron to nature, it is again broken by the stampers, and flourished a second or third time.

The iron is then again pounded, and sometimes mixed with pure scull or scrap iron, and is fit for chaffing or melting in the close pots, with a covering of clay, when it becomes "perfectly tough and malleable," and is to be "wrought under the hammer into half blooms."

MAKING PIG IRON MALLEABLE IN A REVERBERATORY OR AIR FURNACE WITH RAW PIT ONLY.

CRANAGE, THOMAS AND GEORGE.—1766, June 17. No. 851.

"The pig iron is put into a reverberatory or air furnace, built of proper construction, and, without the addition of anything more than common raw pit coal, is converted into good malleable iron, and being taken red hot from the reverberatory furnace to the forge hammer, is drawn into bars of various shapes and sizes, according to the will of the workman."

NOTE.—*We here see the importance of considering the state of the art at the time when the invention was made. After Cort had invented puddling, Cranage's specification would have been, in general terms, a description of that important invention. But before Cort's specification was issued (see abstract of it further on) we doubt if Cranage's would have guided any one "skilled in the art," to puddling. The two words "is converted" stand for the whole process of stirring up the iron with the rabble. The use of raw pit coal, which gave such great value to Cort's invention, is, however, mentioned. (See Percy's Metallurgy, Iron and Steel, p.* 636.)

MORE RAPID DECARBURIZATION IN THE FINERY BY THE USE OF MORE TUYERES AND A MORE DIFFUSED AIR BLAST.

COCKSHUTT, JOHN.–1771, May 2. No. 988.

The patent first describes making malleable iron (if "right managed") in the finery, from ore mixed with cinder.

Pig iron is made into wrought iron by heating sufficient for a bloom or loup in an air furnace, or with bellows. The heated metal is then put into a finery or bloomery, and melted with charcoal until it comes to nature, when it is sunk into a bloom and another charge is supplied. The finery is made of metal plates, open on two or more sides, so that men may work at least on two sides. "Instead of having only one tuiron" for the blast, there are "several tuirons, so as to direct the wind from the bellows to operate upon the iron in every part of the fire." The number of tuirons is regulated according to the nature of the iron. "This new finery, and new method of working, requiring a greater supply of wind than the common way," an air reservoir with valves is constructed to regulate the blast, the supply being provided by the requisite number of bellows.

NOTE.—*Ninety-eight years ago this iron worker had a better appreciation of the theory of air refining, which has since been so successfully worked out by Bessemer, than some of Bessemer's competitors have to-day. The idea of diffused blast is one of the leading ideas of Bessemer's invention, and if Cockshutt had blown a little harder, so as to penetrate the metal, he would have made a loup malleable in whole or in part, but he would not, of course, with any means then known, have produced his malleable metal in a liquid state. Some of the early claimants of the Bessemer invention used but one tuyere, and did not diffuse the blast.*

MAKING "STEEL" OR A HIGH IRON LIKE PUDDLED STEEL DIRECTLY FROM PIG IRON IN A BLOOMERY.

GOODYEAR, JAMES.—1771, Dec. 20. No. 1,000.

"Place the pig or cast iron in the fire as when you intend to make bar iron, but the blast of the bellows must not be so strong. When some of the iron is sunk in the fire you must work from the bottom as when you make iron, but keep melting iron as at first. When there is a sufficient quantity to make a loup let the whole sink to the bottom," when it may be fused and shingled, and drawn as common iron. "The fire must be kept as free from cinder as possible. The addition of common salt and other saline substances," and animal or charcoal dust, improves the steel. "The finest steel, after it is made as above, may be converted in the same manner as common steel is made from bar iron."

NOTE.—*The decarburized iron appears to be recarburized by keeping the pig iron melting above it after it is sunk in a loup, and also by charcoal dust, and it may be further recarburized by "converting."*

Steel is here mentioned by name, for the first time in the patent records.

MAKING MALLEABLE IRON FROM PIG, WITH RAW COAL OR COKE, WITHOUT GRANULATIONS OR ADMIXTURES, FROM BROKEN AND WASHED FINERY IRON.

JESSON, RICHARD, AND WRIGHT, JOHN. —Oct. 30, 1773. No. 1,045.

Pig iron, or scull or cinder iron, is melted in a finery with blast and with raw coal only, and taken out in lumps while hot, beaten into plates by a flat stamp or hammer, broken small and well washed by hand or in a rolling barrel. The broken metal is then melted in an air furnace or in closed pots and then "beaten into bars from a chaffery in the common way." If the metal be red short or cold short, it is mixed in the pots with the proper quantity of scrap or nutt iron.

NOTE.—*There appears to be nothing new or feasible here, except the washing in a rolling barrel, if red short iron, which the patentee mentions, was used; the lumps taken out of the finery and hammered would not require much farther breaking up, even if the carbon were sufficiently removed to render the mass malleable. If he made this process work, he has not told us how.*

FLUID IRON FROM THE SMELTING FURNACE STIRRED AND WORKED (AND IT WOULD APPEAR) PUDDLED IN AN AIR FURNACE BY THE AID OF AIR BLAST AND WATERY VAPOR.

ONIONS, PETER.—1773, May 7. No. 1,370.

Two furnaces are used, a common smelting furnace and another furnace of stone and brick, "bound with ironwork and well annealed," into which the fluid iron or metal is received from the smelting furnace. "A quantity or stream of cold water is run or put into the cistern or trough under the ash-grate." The furnace is then charged with fuel and closed up, and the doors luted with sand. The blast is then admitted below the grate, and when the furnace is sufficiently heated the liquid iron metal is taken from the smelting furnace in ladles, and introduced through an aperture, which is then closed. The blast and fire are then used "until the metal becomes less fluid and thickens into a kind of paste, which the workman by opening the door turns and stirs with a bar or other iron instrument, and then closes the aperture again, and must apply the blast and fire until there is a ferment in the metal." If no ferment ensues, a blast of cold air is to be blown upon the metal from an extra pipe. "As the workman stirs the metal" the scoria will separate, "and the particles of iron will adhere," these the workman "must collect or gather into a mass or lump." This is to be reheated to a white heat, and then taken to the forge hammer and forged into malleable iron. Instead of running fluid metal into the furnace, pig iron may be placed and melted there, and operated upon as above described. The forge hammer is connected with an air cylinder whose piston is attached to the helve, and is worked by it. The cylinder is either placed above the helve and acts as a buffer on the compression principle, or is placed below and on the exhaust principle draws down the hammer.

NOTE.—*It is difficult to see, from the patent records, why this patent does not in a great degree anticipate Cort's. Onions' drawings show a reverberatory furnace, and not a bloomery or finery fire in which the fuel and iron might be mixed together. The stirring with a bar, the ensuing fermentation, the coming to nature and the aggregation of the puddle ball, are distinctly described. (See also Percy's Metallurgy, Iron and Steel, page* 638.)

The direct blast of air would not be considered an element in puddling, as explained now-a-days by Mr. Siemens. (See Van Nostrand's Mag., Vol. 1, *No.* 1, *page* 38.)

A considerable quantity of steam must have been formed under the grate, and passed over with the flame. The modern Pomeroy process revives this practice.

*Peter Onions was a successful iron maker; his knowledge of the subject—*96 *years ago—was certainly in advance of the times.*

PUDDLING.

CORT, HENRY.—1784, Feb. 13. No. 1,420.

On Jan. 17, 1783, Mr. Cort patented a process of faggoting bar iron and of welding by *rolling in grooved rollers.* The title of the puddling patent of 1784 is as follows: "Shingling, welding, and manufacturing iron and steel into bars, plates, rods, and otherwise, of purer quality in larger quantities by a more effectual application of fires and machinery, and with greater yield than any method before attained or put in practice."

The patentee uses a reverberatory furnace heated by coal, having a concave bottom, into which the fluid metal is run from the furnace, or pig iron is put in and melted. When the workman discovers, by looking through a hole, that the metal is sufficiently melted, he opens an aperture, by preference, in the bottom of the door, and works and stirs up the mass of metal with iron bars, "which operation is continued, as may be requisite, during the remainder of the process." An ebullition of the metal soon takes place, and the stirring with the bar is continued till the metal is "flourished and brought to nature," when it is collected in loops and drawn out of the door. All small pieces that may happen to remain are cleared away. These with scull and parings and nut iron may be thrown into the furnace and worked up with the iron while it is being brought to nature. The iron so prepared may be stamped into plates, broken, piled, and worked in an air furnace, in pots, or without. "But the method invented by me is to continue the loops in the same," "or reheat them" in another air furnace to a welding heat, and then shingle them into half blooms or slabs. These may be heated in the chaffery, "but my new invention is to put them again in the same or another air furnace" from which the half blooms or slabs are taken, and either drawn down under the hammer or rolled through grooved rollers at a welding heat. Iron and steel so prepared is of good quality, whether the blistered steel be made from fagoted iron or from iron made by the above process. "The whole method" is "completed without using finery, charcoal, cokes, chaffery, or hollow fire without requiring any blast" or "the use of fluxes."

NOTE.—*This patent, and the patents of Nielson, (hot blast), Heath (carburet of manganese in steel making), Bessemer, Mushet, (recarburization), Siemens, and we may perhaps add, the process of Ellershausen, are the most remarkable in the history of the iron manufacture. With the exception of Bessemer's process, Cort's has made a greater revolution in refining iron, and has stimulated and cheapened production in a greater degree than any other process.*

Puddling "without the use of fluxes," however, as specially stated by Cort, has already gone out of use, and the improvements that are created by or will grow out of the Ellershausen process, are likely to revolutionize puddling to as great a degree as puddling revolutionized blooming. In the best practice, the ore used in fettling supplies the waste caused by the oxidation of iron in the puddling furnace, and improves the quality of the product. More recent experiments in the puddling furnace, with as much as 30 *per cent of ore, pulverized and worked into the melted iron, have increased the yield from six to eight heats per day, thus decreasing the cost, and at the same time making good the waste of iron, and improving the quality of the product.*

(To be continued.)

EMPLOYMENT OF COTTON WASTE AS MANURE.—M. Dupont-Poulet, a French cotton spinner, has for the last ten years used his cotton waste for seed beds and early crops. He mixes it carefully with stable manure, and thus avoids, as he says, the burning and the chills which manure alone often causes. M. Dupont-Poulet's example has been followed by his neighbors, some of whom have gone beyond him; one of them had the idea of using cotton in the forcing of asparagus, that is to say, he spread a layer of cotton waste, about eight inches thick, over one of his asparagus beds, and found that the snow when falling upon it disappeared very rapidly; he was able, without any other covering but the cotton, to gather fine, tender, well-flavoured asparagus in the midst of winter.

POWER CONSUMED BY DRILLS.

EXTRACTS FROM A REPORT BY CAPTAIN CLARINOAL, PROFESSOR IN THE ARTILLERY AND ENGINEERS' SCHOOL AT METZ.

Translated by John B. Pearse.

In order to ascertain the power required to bore a hole of given diameter in wrought iron, the following points must be considered: The kind of iron, the direction in which the hole is bored, its depth and diameter, the lubricating material, the form of the drill and its speed. The experiments were conducted with an ordinary drill press, while the power consumed was measured by Morin's dynamometer. The wrought irons used in the experiments were a very hard variety, forged under the steam hammer at the forges at Montigny-les-Metz, and a soft rolled iron from the iron works at Abainville. The drills used were center-bits and a flat drill of exactly equal diameter, driven at the same speed, and lubricated with oil and afterwards with soap-suds. Cast iron, bronze and steel were then similarly experimented on. The conclusions derived from the above experiments were the following:

(1.) The amount of power necessary to drill with a center-bit into wrought iron, remains quite constant so long as the depth of the hole does not exceed 0.05 meter: as soon as this limit is passed the required power increases rapidly.

(2.) The power consumed in boring across the fibres is almost independent of the depth of the hole; the original power is, however, somewhat greater than that required to drill in the other direction. Since however the power required in boring in the latter direction increases greatly with the depth, the total power required to bore a given hole across is much less than that required to bore it in the direction of the fibres.

(3.) The power required to bore a hole of given diameter increases with the hardness of the iron. The use of oil to lubricate the drill diminished the power required about 0.2, as compared with that required when soap-suds were used. This holds good as well in hard as in soft wrought iron.

(4.) The results obtained with center bits hold good also for flat drills; the latter, however, require a greater power than the former, as is shown below.

(*a*.) The power required by a flat drill 0.025 meter in diameter, to bore a hole in the direction of the fibre, is about 1.25 times as great as that required by a center bit of similar diameter operating under similar circumstances.

(*b*.) The power required by a flat drill, 0.025 meter in diameter, to bore across the fibres, is about 1.4 times as much as that required under similar circumstances by a center bit.

(*c*.) When the diameter of the drills is 0.015 meter the above quantities become 1.6 and 1.8 respectively, which seems to show that small drills require a comparatively greater power than large ones. When the diameter of the drills is 0.008 meter, the above proportion becomes 1.52, which corroborates the above conclusion.

These results agree with practice, since the flat drill is commonly used only for holes 0.008 meter in diameter, and under, which do not permit the use of the center bit or pin drill.

EFFECT OF VELOCITY.—In order to estimate the effect of the velocity of the drill, a drill of 0.025 meter was driven at a speed (on its circumference) of 0.22 meter per second, and also at a speed of 0.125 meter. The power consumed per second is clearly less at a slow speed than at a high one, but the power required to bore a given hole is about the same in each case. For instance, the power required to bore a hole 0.0074 meter deep (in the direction of the fibres) at a speed of 0.22 meter, amounted to 23.49 meter-kilogrammes, and to 21.8 at a speed of 0.125 meter: across the fibres, the power required at the high speed was 24.3 meter kilogrammes, and 22.3 at the low speed.

It appears then that the power required to drive the drill at either speed is not very materially different. Hence, the reporter concludes that the speed of the drill should be as great as possible, to diminish the resistance offered by the metal, and that the feed should be heavy, and both so far as possible without destroying the edge or boring too rough a hole.

The average advisable circumference speed of drills is 0.12 meter per second in wrought iron, 0.06 meter in cast iron and 0.15 to 0.18 in bronze (gun metal). When these velocities are exceeded the drill is apt to become soft, and when they are not reached the work is not economical.

The pulleys of the drill press used for these experiments are so calculated that the following circumference speeds of drills could be obtained:

	Millimeter.	Millim.	Milim.
Diameter of drill...	3 to 10	10 to 20	20 to 25
Speed at circumference............	34 to 115	77 to 154	104 to 183
Feed	16	10	7.5 milim. per min.

POWER DEMANDED BY BORING MACHINES.—As the hardest wrought iron necessitates the most power, M. Clarinoal based his experiments on that forged at Montigny, which is generally acknowledged to be very hard, and compiled the following tables from the results of numerous experiments on this wrought iron, on east iron and on bronze. The first table denotes the power required by a center-bit in boring a hole of given diameter and depth, while the second table gives the eorresponding results in the case of a flat drill.

Table showing power required in one second by a center-bit boring at different depths in hard wrought iron, ordinary gray cast iron, and gun metal (11 *parts tin and* 100 *parts copper*), *the feed being one millimeter per minute.*

	Lubricated with soap-suds.			Bored dry.		Bored dry.	

As the results in wrought iron apply to hard iron, they should, according to M. Clarinoal, be diminished by about one-tenth to apply to soft wrought iron; and as the experiments were made with soap-suds as lubricating material, the powers given should be diminished, say one-fifth, when oil is used as the lubricator.

In the above tables, the power consumed by boring the given holes with a feed of *one millimeter per minute*, is taken as unity. Therefore, to ascertain the power required *in a second*, with a given feed, it is only necessary to multiply the figures in the tables *by the depth fed per minute.*

A comparison of results obtained with borers of both kinds of the same diameter (0.25 meter), shows that the power required to drive a flat drill in cast iron is 2.6 times as much as that required to drive a center bit.

Experiments on hard white cast iron, showed that the power required to drill such iron was very nearly double that stated for gray cast iron. It appears from the tables that the power required to drill cast iron is nearly constant, no matter what the depth of the hole may be.

The experiments made on steel showed that, under similar circumstances, more power was required to drill shear or soft steel than to drill hard cast steel, and that flat drills increased the power necessary by at least one-third ($\frac{1}{3}$).

Capt. Clarinoal concludes with the following remarks:

(1.) Nearly the same power is required to drill hard wrought iron and hard cast steel.

(2.) The power required to bore soft steel is not much greater than that required for hard wrought iron, but the former increases rapidly with the depth of the hole. Thus, at a depth of five or six millimeters, the power consumed in drilling with soap-suds in soft steel, a hole fifteen millimeters in diameter, is equal to that consumed in boring one of twenty-five millimeters in diameter in hard wrought iron.

HYDRAULIC PIPE ENGINEERING. — Messrs. Walsh and Watkins, contractors, have laid a 11-inch plate iron water-pipe, from a point on a mountain side in Tuolumne county, California, down the mountain, under a creek and up the ascent on the other side, in all 8,800 feet in length, and under a perpendicular pressure at the lowest point of 684 feet.—*Mining and Scientific Press.*

PURIFYING IRON ORES.

ON FLUOR SPAR AS AN AGENT FOR PURIFYING IRON ORES CONTAINING PHOSPHORUS.

By H. CARON.

Translated by John B. Pearse, from "Comptes Rendus" and "Berg and Hütten Zeitung."

I have already had the honor of communinicating to the Academy the results of my attempt to improve those pig irons which are smelted from non-manganiferous ores, which ores form a great part of those occurring in France. I was enabled to show by exact experiments that the addition of manganese (in the form of its oxides) to the furnace charges had the effect of removing or keeping out of the iron an appreciable quantity of the sulphur and silicium present in the ores and fuel. Since that time the experiments of the laboratory have been carried out in the trade, and there are now few furnaces where the addition of the oxides of manganese has not brought about a marked improvement in the quality of the pig metal.

I found at that time that the oxides of manganese had no effect in carrying off phosphorus, although they acted so favorably upon sulphur and silicium. I therefore endeavored to find some means of effecting the removal of the former body, and now confine myself to the communication of the only method which has given satisfactory and certain results.

The ores of iron which contain phosphorus, contain it principally in the form of phosphates of iron, alumina or lime; in order to combat the evil effects of these phosphates it was customary to mix large quantities of lime with the ores, as lime was commonly supposed to have some effect in this direction. Unfortunately, however, these phosphates of lime are slightly, or rather not at all fusible, and the addition of large quantities of silicious ore was necessary to cause the slag to flow readily.

What is now the result in the blast furnace? Phosphates, silicia and carbon are in immediate contact—just as in Wökler's method of preparing phosphorus; there result therefore silicious slag and iron, carbon and free phosphorus, which latter naturally combine to form a cold short pig metal. It is certain that this re-action actually occurs in the furnace as the analysis of slags, from ores containing a good deal of phosphorus, show very little of this element, while it is very rare that the same is not present in injurious quantity in the iron. Let us suppose that lime takes up the phosphorus of the ores, the problem then before us is to find some fusible substance which contains no silica, and can dissolve the phosphate of lime, without decomposing it. It seemed *a priori*, as if fluor spar was such a substance, and I endeavored to ascertain its virtues as follows:

(1.) A mixture of phosphate of lime and fluor spar was placed in a crucible of compressed coke, which was placed in a clay crucible and surrounded with charcoal.

(2.) A mixture of phosphate of lime with silica was placed in a similar crucible. Both crucibles were then exposed to the heat of a cast steel furnace, with the following results: The crucible containing the phosphate of lime with silica was eaten completely through, and the phosphorus had disappeared. The other crucible, on the contrary, was whole, merely a little of the coke alone having been melted off; the fused mass contained phosphorus and phosphoresced when struck with a hammer. It was therefore certain that fluor spar dissolved the phosphate of lime without decomposing it.

I accordingly experimented as follows upon phosphate of iron:

(1.) A mixture of phosphate of iron with lime and fluor spar, was placed in a brasqued crucible.

(2.) A mixture of phosphate of iron with lime and silica, was also placed in a similar crucible.

These mixtures treated as before gave the subjoined results. The crucible containing silica was eaten through, and the graphitic button of iron was easily broken up under the hammer. The other crucible was whole, and the resulting button was somewhat flattened out before it could be broken up, while the fracture showed that the iron was mottled. The first button contained three (3) times as much phosphorus as the second, which on being remelted became entirely white. The influence of the fluor spar was therefore established beyond a doubt.

On operating analogously upon ores containing phosphorus, which always contain a comparatively small quantity of phosphates, an appreciable improvement resulted from the substitution of the fluor spar for silica, although the improvement became less marked, the less phosphorus the ore contained. Not only are these phosphates soluble in fluor spar but also sulphates and arseniates; even alumina is taken up by this agent and retained in the slag without the aid of silica.

GOVERNMENT CONTROL OF TELEGRAPHS IN ENGLAND.—The acquisition of the telegraphs of the United Kingdom by the Government, and their being placed under the Post-Office administration, had been mooted for some time; last spring, action began to be taken and inquiries made; the result has been a large correspondence and cross-fire of pamphlets between the Post-Office and telegraph companies. This cleared the way for the government bill, which, after being committed, and much time spent in discussing and amending its objects, finally passed both Houses of Parliament and became a law. It empowered the Post-Office to buy up all the telegraph systems of the various telegraph companies of this country who were willing to sell their property. This all have been found willing to do, and meetings have been held authorizing the directors to agree to the Post-Office terms, which have been usually a twenty years' purchase on present rates. The final amount to be paid to the various telegraph companies has to be settled by arbitration. Agreements have also been entered into between the Postmaster-General and the various railway companies, by the which it is settled that all wires belonging to the railway company, and used by them for their special services of train signalling or otherwise, shall remain theirs, in addition to which the railway company will in future maintain all wires, poles, and telegraphs, the property of the Government, passing over their lines. Under this arrangement, there may be perceived the following curious change—what the telegraph companies formerly did and still do for the railway companies the railway companies will now do for the Government.

The Post-Office are making great internal changes preparatory to taking charge of the telegraph system, and to complete the transfer it is now only necessary to bring into Parliament the bill for providing the necessary funds. It is anticipated that this will be done very early in the year, and by July 1 it is most probable that the various telegraph companies will have handed their systems over to the Government.—*Mechanics' Magazine.*

THE HEATON PROCESS.—The discussion on the merits of this process, still occupies many dreary pages in the London newspapers. Nothing very new or important has been elicited. We shall, in a future number, give a very brief abstract of the situation up to date.

THE MOLDAU SUSPENSION BRIDGE AT PRAGUE.

The peculiarity of this bridge is that there is only one pier, or tower, and that is in the center of the river, so that the bridge is really formed of only two half spans, each half being in the clear 305 feet six inches, the thickness of pier being eighteen feet at the crown. The distance from face to face of abutments is 629 feet; on each shore there is no room for the anchorage chains, &c., to extend such a distance inland as would be required if towers were used instead of abutments. And it was considered advisable to have only one pier or tower in the river, to avoid as much as possible intercepting the ice.

The particulars of the work are thus given in "Engineering": The bridge is for foot passengers only, and has a clear width of eleven feet from end to end. Each column of the pier being built clear of this width involves the chains being wider apart, in plan, in the center of the bridge than at the abutments; this arrangement gives the structure considerable resistance to any side motion that might be caused by the wind.

The abutments and anchorages are built of stone, with concrete fillings. The pier in the center of the river is also of stone from its base to the underside of the superstructure, where the ornamental cast-iron tower commences. The tower consists of two pillars or columns connected at the top by an open cast-iron girder, and each column consists of four standards firmly connected together and bolted at their bases to the pier. The height of the bridge above the highest level of water is six feet six inches, and height of tower from same level is 63 feet.

The chains are of steel, and formed of links in 21 feet lengths by four and a half inches deep by one inch thick, having heads and eyes, and steel pins of three and a half inches diameter. The main chains have each six links in width, and they are connected to straight chains which pass direct to the base of the tower. These straight chains are applied to prevent as much as possible the rising or moving of the curved chains when an unequal load is passing over the bridge. The straight chains have only two links each of the same dimensions as the links of the curved or main chains. The main chains are supported on the tower on a saddle resting upon seven cast-iron rollers, each three feet long and four and a half inches diameter, and carefully turned, from whence they pass to the abutments, where they rest on other saddles, and from thence they pass to their anchorage. The anchorage for each end of each main chain consists of seven steel plates resting upon two cast-iron girders or bed plates, the four bed plates being connected together by cast-iron girders. The connections for the adjustment of the lengths of the main chains are near the tower and in the abutments, and for the straight chains at the base of the tower, and can be adjusted by means of steel gibs and keys.

The footway or platform is formed of two main longitudinal parapet girders in one continuous length from end to end of bridge, and rests upon cast-iron cross girders twenty-one feet apart, which are suspended by wrought-iron suspension rods one and a half inch. diameter, to the main chains. The main or parapet girders are one foot six inches deep, the top and bottom flanges being formed each of two pieces of pine, having a total sectional area of 72 square inches. The diagonals are also of pine, six inches by three inches, fitted into cast-iron shoes cast on the ends of the C I verticals; these have a wrought-iron bolt one inch diameter passing through them, firmly connecting the bracing to the flanges. The verticals aro seven feet apart, and at these distances there are cross timbers acting as girders to support the planks of the footway, so that there are two timber beams and one cast-iron girder in every 21 feet to carry the planking of the footway. The planking is four inches thick, and on this is boarding one and half inch. thick, laid crosswise. The footway, besides being suspended to the chains, is also connected to the base of the tower by means of four diagonal rods, which allow it to move only vertically to a slight extent, but not horizontally.

The quantity of cast iron contained in the tower saddles, anchorage girders, cross girders, verticals in parapet girders, &c., is 108 tons. The steel in the chains, plates and pins is 78 tons, and four tons of wrought iron in bolts, &c. There are 5,600 cubic feet of timber work in the platform.

The bridge will have to stand a test moving load of 96 pounds per square foot, and will not give a greater strain on the steel chains than twelve tons per square inch, and the breaking strain of the steel is 36 tons per square inch. The links are being made at the Cyclops Steel and Ironworks, Sheffield, and the other work is being made at Prague. The pier and anchorage and abutments are now complete, and the anchorage chains are in place. It is to be opened for traffic on the 1st of November of this year.

The design was made by Mr. R. M. Ordish, and is being executed by the same contractors who had built the Franz Joseph Bridge, viz., Messrs. Ruston & Co., Prague. Charles Von Wesseley is the resident engineer. The contract for the structure has been taken for £18,500.

THE METAL HYDROGEN.

Based on its chemical and physical properties, the opinion has long been held that hydrogen is a metallic element. Though only known to us in the form of a gas which has hitherto resisted all our endeavors, by pressure and cooling, to cause it to change its state of aggregation, and condense to a liquid or take a solid form, it cannot fail to be recognized that its existence in this condition only, depending as it does on the imperfection of our scientific instruments, in nowise invalidates the doctrine of its metallic nature. The attempts to condense hydrogen were unsuccessful on account of the difficulty of rendering vessels absolutely tight at such enormous pressures. Mercury, on the other hand, is liquid at ordinary temperatures; zinc, magnesium, and other metals are readily converted into gas, and gold and silver can be volatilised in the electric arc. Platinum, which Faraday melted in the flame of a candle, can doubtless be dissipated as vapor. The failure, therefore, to solidify hydrogen at present proves nothing.

The difficulty of condensing hydrogen has recently been attacked from another direction. About a year ago the Master of the Mint startled the scientific world with the announcement that he had extracted hydrogen from iron.

He placed a piece of the Lenarto meteorite in vacuo, and on subjecting it to heat drew from this iron several times its volume of hydrogen. This gas which, when free, so readily diffuses that it cannot be preserved for many days in a tube over mercury, but passes between the mercury and the walls of the tube and escapes into the air, was so firmly combined with the iron that, not the removal of atmospheric pressure alone, but the application of heat also, was required to effect their separation.

Recently Mr. Graham communicated to the Royal Society another paper on this interesting subject. He now employs a metal that absorbs hydrogen, as melted silver or platinum black does oxygen, or water ammonia. Palladium occludes from eight to nine hundred times its volume of hydrogen, and he regards the product as an alloy of palladium with the volatile metal hydrogen, in which the volatile character of the one metal is restrained by its chemical affinity for the other, but which owes its metallic characters to both. The alloy has a density considerable less than that of palladium, and he has been enabled to calculate that of the metal hydrogen, which he finds to be 1·951. Hydrogenium, as the new alloy is called, is more magnetic than palladium, in the ratio of 48 deg. to 10 deg., and must be considered to forsake "the class of paramagnetic metals, to take a place in the magnetic group of iron, nickel, cobalt and others." The occlusion of hydrogen by palladium reduces its tenacity and electric conducting power.

The strongly marked magnetic character of hydrogen, the readiness with which it forms alloys of such great permanence, and, more especially, its occurrence in combination with iron in meteoric masses, are facts of special interest at the present time, now that the spectroscope has revealed the existence of such enormous quantities of this element in our system.—*The Engineer.*

THE STRENGTH OF CORRUGATED IRON.

As a supplement to Mr. J. H. E. Hart's paper on this subject,* we publish the following letter by him to the "Bombay Builder":

Sir—Referring to experiments on the strength and stiffness of corrugated iron, published in your journal August, 1868, I have to suggest to your readers the following formula for the deflection of the material, obtained from equations in Professor Rankine's work. At page 328, article 303, of the third edition of "Applied Mechanics," is the general equation—

$$\sqrt{\frac{\prime}{1}}=\frac{n''M'_0c^2}{E\,I_0} \quad . \; . \; . \; . \; . \; . \quad (25)$$

for the "deflection of a beam under any load," in inches. In this formula $c = l$, or $\frac{l}{2}$, according as the beam is fixed at one end only, being unsupported at the other, or supported at both. Confining ourselves to the case of sheets supported at both ends, the above equation becomes—

* Van Nostrand's Magazine, Vol. I, No. 2, p. 129.

$$\surd'_1 = \frac{n'' M'_0 l^2}{4 E I_0} \;.\;.\;.\;.\;.\;.\; (26)$$

The values of M'_0 are those already given for M in equations 10 and 11, at page 95 of Vol. IV. of this journal; n'' is a factor depending on the distribution of the load, and is, for beams loaded in the middle $= \frac{1}{3}$, and for beams loaded uniformly $= \frac{5}{12}$.

E is the modulus of elasticity of wrought iron in pounds; I_0, the moment of inertia of the cross section of the beam. We may, I think, adopt the value of I_0 for the cross section of corrugated sheets obtained from the equations for the transverse strength of the material. The general equation for the moment of resistance of a beam (see "Applied Mechanics," article 294) is $\frac{f I^o}{Y}$, and the value of $y = m' h$; also, as for all symmetrical sections $m' = \frac{1}{2}$, therefore $Y = \frac{H}{2}$ whence the moment of resistance $= \frac{2 f I_0}{H}$

But, as already mentioned, the moment of resistance (see "Civil Engineering," page 543) for corrugated sheets is $\frac{4}{15} f\,h\,b\,t$, and this equals $\frac{2 f I_0}{H}$, whence

$$I_0 = \frac{2}{15} h^2\,b\,t. \;.\;.\;.\;.\;.\; (27)$$

and equation 26 becomes for corrugated iron generally

$$\surd'_1 = \frac{15\,n''\,M'_0\,l^2}{8\,E\,h^2 b\,t}. \;.\;.\;.\; (28)$$

and for the following particular cases:—

SHEETS SUPPORTED AT ENDS.

For central loads, $\surd'_1 = \frac{W\,l^3}{6{\cdot}4\,E\,h^2\,b\,t}$. (29)

For distributed loads. . . . $\surd'_1 = \frac{W\,l^3}{10{\cdot}24\,E\,h^2\,b\,t}$. (30)

E, the modulus of elasticity, may be deduced from the experiments under reference by the formula

$$E = \frac{W\,l^3}{6{\cdot}4 \surd_1 h^2\,b\,t}. \;.\;.\;.\; (31)$$

which, using the data obtained, gives values for E ranging from 21,000,000 to 30,000,000, being, on the average, 25,000,000; or it may be taken from any of the published results on the elasticity of wrought iron. Thus, in Professor Rankine's work we find E = 29,000,000 for bar iron; also E = 24,000,000 as a "good average" for plates. For the case of sheets fixed at both ends the deflection is (article 307, "Applied Mechanics")—

$$\surd'_1 = \left(n'' - \frac{m''}{2}\right) \frac{M_0\,c^2}{E\,I_0}. \;.\;.\; (32)$$

In this formula $m'' = \frac{1}{2}$ or $\frac{2}{3}$, according as the load is collected in the center or uniformly distributed; and in both cases the value of $n'' - \frac{m''}{2} = \frac{1}{12}$, also c^2 as before $= \frac{l^2}{4}$ and as the case may be; therefore equation 32 becomes,

IN SHEETS FIXED AT ENDS.

For central loads—

$$\surd'_1 \frac{W\,l^3}{192\,E\,I_0} = \frac{W\,l^3}{25{\cdot}6\,E\,h^2\,b\,t}. \;.\; (33)$$

For uniformly distributed loads—

$$\surd'_1 \frac{}{384\,E\,I_0}\;\frac{W\,h^3}{51{\cdot}2\,E\,h^2\,b\,t}. \;.\; (34)$$

Hence, it appears, sheets are made stiffer by fixing their ends, in the ratio 4 : 1 for central loads and 5 : 1 for uniformly distributed loads. We see from previous equations that they are made stronger in the ratio 2 : 1 and $1\frac{1}{2}$ to 1 respectively.

In calculating values of E from the experiments, it is advisable to reject the first weight and its deflection, basing the calculations on the difference between the first weight and deflections and those of a value of somewhere about one-third the breaking weight. The reason for this precaution is that any error due to the first settling of the sheets to their bearings may be eliminated from the result.

SAFETY OF STEAMSHIPS.—A correspondent of the London "Times" proposes to clear steamers of water entering by leakage or shipped in heavy weather, by means of steam jets arranged something like the Giffard injector, and worked with the full boiler power, if necessary, so as to discharge, say, 1,000 cubic yards of water per minute. It certainly seems unnecessary for a ship with 1,000 to 5,000 horse power, all in working condition, to founder for the want of means of application. The jet proposed would be simple and always ready to work. Centrifugal pumps would, perhaps, accomplish more, keep the ship afloat with a bigger hole in her, and might be kept always in order.

THE HERCULES IRON-CLAD.

REMARKABLE PERFORMANCE — PARTICULARS OF THE ENGINES, THE VESSEL AND THE TRIAL.

Compiled from "Engineering" and "The Engineer."

The attainment by an iron-clad frigate, at her deep-load draught, of a speed of 14.7 knots, or over seventeen miles per hour; and the development of 8,528 indicated horse power by a pair of marine engines weighing with their boilers, water, etc., complete, but 1,095 tons, are facts, the importance of which it is impossible to overrate. These results were obtained on January 1st, by the Hercules, and are extremely creditable to her designer, Mr. E. J. Reed, and especially so to Messrs. Penn, constructors of her engines.

Description of the Vessel.—The Hercules is the latest, and the representative broadside ship of the British navy, and is of the following dimensions:

	ft.	in.
Length	325	0
Breadth	59	0
Draught forward	23	0
Draught aft	26	5
Tonnage	5,234 tons.	
Displacement	8,680 tons.	
Midship section	1,315 sqr. ft.	

Her armor consists of a belt of plating, extending from five feet below the water line to nine feet above it, this belt being surmounted by the central battery, whilst at the stem and stern are the armor-clad batteries in which the fore and aft guns are placed. At the water line the armor consists of nine inch plates, backed by 40 inch. of teak, whilst above this belt the thickness of the plates is reduced to eight inch. and six inch. The ends of the central battery are protected by six inch plates. The armament comprises eight eighteen ton guns, throwing 800 pound shot, placed in the central battery; a twelve ton gun, throwing 250 pound shot, mounted under the forecastle behind armor-clad ports; a similar gun, mounted in the captain's cabin, in an armor-clad stern battery; and four six and a half ton guns, throwing 115 pound shot, placed on the upper deck, and fought through unarmored ports. Of the eight eighteen ton guns, four can be fought through the ordinary side ports, the sills of which are eleven feet above the water line, whilst the other four can be fought from ports at the angles of the central battery, and can be fired within fifteen degrees of the centre line of the vessel. The twelve ton guns can be fired directly in the line of the keel, the one forward, and the other aft, whilst they have each also a considerable lateral range. Besides possessing a most powerful armament, the Hercules has been so constructed that she may be used for ramming purposes, and for such a method of attack her great handiness and high speed peculiarly fit her.

Description of Engines.—These are trunk engines, by John Penn & Son. They are fitted with surface condensers, exposing 20,768 square feet of surface, the condensing water being supplied by a pair of centrifugal pumps, arranged so that they can be made to draw from the bilge, and capable of delivering 120 tons of water per minute. The circulating pumps are driven by a pair of independent engines.

Steam is supplied by eight boilers, having 40 furnaces, the fire-grate surface being 907 square feet, and the total heating surface 23,100 square feet, of which 19,792 square feet are tube surface. The boilers are fitted with eight superheaters, containing, in all, 3,908 square feet of surface.

Number of cylinders	2
Diameter of cylinders	127 in.
Diameter of trunks	47 in.
Effective diameter of cylinder	118 in.
Stroke	4 ft. 6 in.
Nominal horse power	1,200 H. P.
Load on safety valves	30 lb. per sq. in.

Temperature of steam in superheater from 305° to 310°.

Propeller.	Description	Griffiths' varying pitch from 20 ft. 6 in. to 25 ft. 6 in.
	Diameter	23 ft. 6 in.
	Pitch	24 ft.
	Length	4 ft. 7 in. at root of blade, 1 ft. 3 in. at periphery of do.
	Immersion of upper edge	1 ft. 11½ in.

Of the machinery of the Hercules, and of its performance, it is impossible for us to speak too highly. As specimens of excellent design, combined with the very best workmanship which even Messrs. Penn can produce—and their workmanship is certainly unsurpassed, and in but very few cases equalled—the engines of the Hercules stand unrivalled, whilst the power developed by them by very far exceeds that ever obtained on shipboard from any engines, under any circumstances whatever. Mr. Penn has long taken the lead in the adoption of high speeds of piston, and the success he has obtained has decisively shown the advantages of such speeds, when accompanied, as they should be, by first-class workmanship.

The Performance.—The trial at Stokes Bay, on January 1, consisted of six runs over the measured mile, under full steam, and four runs under half-boiler power, under the conditions of craft mentioned above, and with the following particulars of power, speed, etc.:

	Full power.	Half power.
Pressure of steam in boilers	29. 5 lb.	21.87 lb.
Vacuum in condensers — for'd.	27.08 in.	28. 5 in.
Vacuum in condensers — aft	27.08 in.	28 in.
Number of revolutions — max'm	72.00	58.52
Number of revolutions — mean	71.51	55.29
Mean pressure in cylinders	20.00 lb.	12.268 lb.
Indicated horse power	8,528.75	4,044.91
Speed of vessel	14.691 knots.	12.122 knots.
Time under way	5 hrs. 25 min.	
Time at full speed without stopping	1 hr. 55 min.	
Weather barometer	30.20 in.	
Wind — Force	2 to 4	
Wind — Direction	S.W.	
State of sea	Smooth.	

Engines stopped from time of moving telegraph .... 19 sec.
Engines started ahead from time of moving from astern .... 14 sec.
Engines started astern from time of moving telegraph .... 16 sec.
State of masts, yards, etc. .... complete.
Quantity of coals on board .... 600 tons, including 70 tons of trial coal.
Armament .... complete.
Quantity of stores .... six months'.

	No. of runs.	Revolutions of engines per min.	Observed time.	Speed due to time.	First mean speeds.	Second mean speeds.
				knots.	knots.	knots.
Full power.	1	71.51	3.47	15.859	14.621	....
	2	70 93	4.29	13.383	14.763	14.692
	3	71.31	3.43	16.143	14.617	14.690
	4	72.00	4.35	13.091	14.764	14.690
	5	71.78	3.39	16.438	14.624	14.694
	6	71.53	4.41	12.811	....	....
		71.51	Mean.	True mean speed.		14.691
Half power.	1	58.42	4.27	13.483	12.394	....
	2	55.51	5.21	11.215	12.036	12.192
	3	54.00	4.40	12.857	12.071	12.053
	4	53.23	5.19	11.285	....	....
		55.29	Mean.	True mean speed.		12.122

The engines exerted rather more than seven times the nominal power. The importance of this fact will be brought into a stronger light by comparing the engine power and displacement of the Warrior, Bellerophon and Minotaur with those of the Hercules. In the official reports we find the following results:

WARRIOR.

Nominal H. P.	1,250
Indicated H. P.	5,092
Displacement in tons	9,214
Pitch of screw	30 ft.
Revolutions of screw	52.6

MINOTAUR.

Nominal H. P.	1,350
Indicated H. P.	6,193
Displacement in tons	10,275
Pitch of screw	25 ft.
Revolutions of screw	54.96

BELLEROPHON.

Nominal H. P.	1,000
Indicated H. P.	6,199
Displacement	7,369
Pitch of screw	20 ft. 1 in.
Revolutions of screw	73

HERCULES.

Nominal H. P.	1,200
Indicated H. P.	8,500
Displacement	8,610
Pitch of screw	24 ft.
Revolutions of screw	71.5

It will be seen from these figures that the Warrior has one horse power to every 1.8 tons of displacement nearly; the Minotaur has one horse power to 1.64 tons nearly; the Bellerophon has one horse power to 1.72 tons, and the Hercules one horse power to 1.01 tons nearly. To this vast excess of power is due the fact that the Hercules is faster than her larger rivals. Calculating from these data the co-efficients according to the usual formulæ, we get:

	Full boiler power.	Half boiler power.
$\frac{\text{Speed}^3 \times \text{mid sec.}}{\text{Ind. H. P.}} =$	488	578
$\frac{\text{Speed}^3 \times \text{disp.}^{\frac{2}{3}}}{\text{Ind. H. P.}} =$	157	186

It is difficult to compare the constants of the Hercules at her full speed with those of other ships, for no other iron-clad has yet steamed so fast at deep-load draught, and, as is well known, the increased speed obtained under such circumstances must be accompanied by a reduction of the constants. The half-power runs seem to show clearly that, for a short ship, her form is very good, as her half-power constants are higher than the Bellerophon's. The respective half-power constants are as follows:

Hercules.	Bellerophon. (at load draught)
578	543
186	171

the speed of the Bellerophon being, then, 12.154 knots, or almost exactly that of the Hercules under similar circumstances. The full-power constants of the Hercules fall below those of the Bellerophon, which vessel gave, on different occasions, when tried at load draught, the following constants: 518 and 163, 534 and 167, and 530 and 166. Considering, however, that, as we have already mentioned, the constants fall with an increase of speed—and especially at very high speeds—the Hercules has given very good results, as the Bellerophon constants just given were obtained with speeds of 14.171 knots, 13.874 knots and 14.023 knots respectively, whilst the speed of the Hercules was, as we have seen, 14.691 knots. It must not be forgotten, however, that as the Hercules stows but 600 tons of coal, she cannot keep the sea at full speed for any time. Six hundred tons of coal are as nothing in comparison with 8,000 horse power or so. The consumption of fuel cannot be much less than fourteen tons per hour. Therefore, in round numbers, the Hercules carries coal enough to steam at full speed for forty-three hours only, or to carry her, assuming her to have a fourteen-knot sea speed, 602 knots only. In this respect she possesses the worst defects of the short iron-clad.

It is important to observe that the weight of the engines complete and of the boilers and water, is but 1,090 tons, or two and a half cwt. per indicated horse power, a weight which is wonderfully small under any circumstances, and particularly so when the size of the engines is considered. The proportions of areas of the heating surfaces, fire-grate surface, &c., to the power developed, are as follows:—

	Per indicated horse power.	
Heating surface	2.7	sq. feet.
Fire-grate "	0 106	"
Superheater "	0.47	"
Condensing "	2.43	"

As to the handiness of the vessel, we have the following particulars. The balanced rudder first used on the monitors by Captain Ericsson, is employed.

Circles made Under Full Power.—Helm to starboard,—Angle of rudder, 40 deg.; turns of wheel, four. Half circle made in one min. 50 sec.; full ditto, four min. Men at the wheel, sixteen. Helm to port.—Angle of rudder, 38 deg.; turns of wheel, four. Half circle made in one min. 50 sec.; full ditto four min. Men at the wheel, sixteen. The diameter of the circle made in each instance was estimated at not more than twice and a half the ship's length.

Circles Under Half Boiler Power.—Helm to starboard.—Angle of rudder, 40 deg.; turns of wheel, four. Half circle made in two min. 21 sec.; full ditto, four min. 36 sec. Men at the wheel, sixteen. Helm to port.—Angle of rudder, 39 deg.; turns of wheel, four. Half circle made in two min. 40 sec.: full ditto, four min. 50 sec. Men at the wheel, sixteen.

Conclusions.—The British authorities conclude that no other navy in existence can boast of the possession of a ship at once so fast, so handy, so impregnable, so strong, or carrying so heavy an armament. The impregnability, the strength, the handiness, and the powerful armament of the ship are due to Mr. Reed, and he may well be satisfied with the honor which this fact does his reputation as a shipbuilder. But the great speed of the ship is due to Mr. John Penn, and it is only by the adoption of a high piston speed that such results could be obtained; and to such speeds, when combined with good design and workmanship, there is no objection whatever. All the expectations formed respecting her have been more than surpassed in the performance of her engines. The builders had counted upon a speed of 65 revolutions, and an indicated power six times the nominal, but so far were the results beyond these, that the engines averaged 71.51 revolutions, or 643.6 feet of piston per minute, and exerted 7.107 times their nominal power, or 8528.75 indicated, giving one indicated horse power to every 2.7 square feet of heating surface, a proportion seldom exceeded even in locomotive practice, with its quick draught and consequently rapid rate of combustion. Of course we are to admit that the runs were not of very long continuance, the coals were hand picked, and fired with little regard to economy, and the heating surfaces were clean. The indicator cards show not far from 25 lb. of water, or 0.4 cubic foot, for each indicated horse power at full speed, or about 3,411 cubic feet in all, being one cubic foot to about 6.77 square feet of surface, a high rate in marine practice, although often exceeded in locomotives. There are some forms of marine boilers—those, for instance, with water tubes—which show, according to Mr. Isherwood's experiments, but one cubic foot of evaporation for every 30 square feet of heating surface, the latter being in the case of the Merrimack, 12,537 square feet, while the steam discharged per hour into the condenser, the steam having been calculated from the indicator cards alone, was equal to but $403\frac{1}{2}$ cubic feet. It is true that this was fourteen years ago, but the same class of boilers is still employed in the American navy.

Steel Rails.—Over 11,000 tons of steel rails are now in use on the Hudson River Railway.

RAILWAYS FOR CHINA.

From "Engineering."

Now that a through communication across the American continent, by means of the Pacific railway, is nearly completed, with a direct route to the chief Chinese ports, a fresh interest has been awakened as to engineering prospect in the Celestial Empire, and engineers are turning their attention so far eastward.

The principles upon which a railway system in China is established, must differ very widely from those which have governed the formation of lines in other new countries. For instance, in India there was a responsible government; throughout it were plentifully scattered the necessary elements for carrying out the undertaking—English energy and enterprise. Even less then than now, was the country burdened with official routine and red-tapeism. Shareholders were liberally guaranteed, and the rapid construction of railways were as necessary for military purposes as for the development of the country's natural resources. Preliminarily, there was only English opposition to conquer—no native prejudices to overcome.

In China, an entirely different moral aspect rules. From Imperial Majesty downwards, jealousy of foreign interference must take the place of hearty co-operation, and Imperial Celestial guarantees would scarcely satisfy capitalists who have had sore experience of European repudiation. The vital military necessity for rapid communication from one part of the country to another is not fully understood; and there exists the difficulty of overcoming national prejudices, which the effacing of the footsteps trodden by a hundred generations must inspire. The insecurity of Government guarantees, the jealousy of Imperial officials, and the prejudices of the people, are there, the principal difficulties to be encountered.

On the other hand, China possesses a vast undeveloped mineral wealth, and the monotonous industry of her 367,000,000, now put forth year by year, for the preservation of life, not for advancement; for the most part, the well-cultivated alluvial territories are level, and on these tracts the vast mass of the population is found, where labor is so cheap and abundant, and where the essentials for railway construction are most easily attainable. The enormous traffic now floated slowly and laboriously down the canals and rivers to the commercial centers would be transferred to the more rapid and cheaper mode of conveyance, and the introduction of railways would be followed by an invasion of western energy to the almost unworked fields which have been closed to the outer world for so many thousands of years.

The British residents in China agree with those missionaries, whose experience is invaluable, that the first experimental line should be made between Canton and Fatshan, a manufacturing town lying fifteen miles to the south of the larger city, and containing paper factories, gun foundries, and other industrial works; at present some half a million passengers are conveyed between the two places by passage boats, and the transit of merchandise is regular and heavy; this line could be completed in fifteen months. Far away to the north, another experimental line could well be made from Tientsin, the terminus of the grand canal, to Pekin, 70 miles distant, a railway which would secure all the traffic from the canal to the capital, and bring the advantages of a railway system under the immediate notice of the Imperial Government.

In sketching out his views as to the most favorable course for the trunk lines of China, Sir Macdonald Stephenson (who proposed a plan of railways for China in 1846) takes the town of Hankow, on the Yangtse-Kiang, as a commercial center, from which the railways would run east to Shanghai for 650 miles, south to Canton and Hong Kong for 850 miles, and north to Pekin for 800; westward the distance to India is 1600 miles. Shorter lines would connect Canton with Samshui, 40 miles distant, and would intercept the traffic now brought down the north and west rivers, at the junction of which Canton is situated. Between Hong-Kong and Canton, an extensive passenger traffic would be obtained by the construction of 90 miles of line. At present, passage boats and four American steamers meet the requirements of trade. Shanghai and Luchow are two important cities between which exists an enormous traffic that could be secured by the laying of 60 miles of railway through a level country. The line from Hankow to Canton, in passing through the Mieling range of hills, where the only engineering difficulties occur, would strike through extensive coal fields, 60 miles north of Canton, and now worked only rudely, and near the surface.

This large and promising field for engineering will not lie much longer fallow. Anglo-Saxon enterprise will soon be at work in it, and it is reasonable to hope that native opposition will soon give way after the first railroad is opened.

THE LAKE CONSTANCE RAILWAY FERRY.

Compiled from "Engineering."

This ferry, for the transportation of merchandise trains, will connect the town of Friedrichshafen on the northeastern, with Romanshorn on the southwestern side of the lake, the distance across being about eight miles. Friedrichshafen is the terminal station of the Royal Wurtemburg States' railway, leading from Ulm, Stutgard and Frankfort. Romanshorn is the terminus of the Swiss Central railway, which runs to Zurich, Lucerne, Berne and Lausanne.

The vessel, which is constructed to carry twelve wagons, is 230 feet long on the railway deck, 40 feet beam, and six feet six inches deep from the top of the floor to the underside of the beams of the railway deck. Her tonnage is 1,753 tons, builders' measurement, and her draught of water does not exceed six feet. The hull of the vessel, together with the deck, deck houses, paddle boxes, paddle beams, and upper works generally, are of iron; and there is also an iron upper deck 80 feet long, placed at a height of about fourteen feet above the railway deck, so that it is clear of the carriages. The railway deck is provided with two lines of rails six feet apart, each line being capable of accommodating six wagons. The form of the vessel is the same at both ends, each end being fitted with a rudder provided with suitable stops. For a length of 100 feet amidships the vessel has a parallel body, and this part is built on the longitudinal principle, the framing consisting of longitudinal stringers two feet wide, with single angle-irons at top and bottom, and transverse frames two feet wide at the bottom and sides, and eighteen inches at the top, with single angle irons at the outer and inner edges. These latter frames are placed eight feet apart, except at the engine rooms, where they are spaced to suit the engines. The ends of the vessel beyond the parallel body are also built upon the longitudinal system as far as possible, but the extreme ends have frames of the usual kind. The outside plating of the hull is one-half inch, and the inside plating three-eighths inch thick, whilst the angle-irons are throughout three and one-half inches by three and one-half inches by one-half inch.

The vessel is divided by transverse bulkheads into nine water-tight compartments, the central compartment being thirty-two feet long, whilst six others are each twenty-four feet long, leaving the end compartments to make up the remainder of the length. In the central compartment are placed the engines, as we shall explain presently, while in the two next compartments, one forward and one aft of it, are situated the boilers and coal bunkers. Besides the transverse bulkheads there are two longitudinal bulkheads, which are placed twenty-two feet apart, and which extend the whole distance between the extreme transverse bulkheads. The railway deck is made of plates planed at the edges and butt jointed, and it is carried by transverse beams eighteen inches deep, and placed eight feet apart, these beams being firmly rivetted to the skin, and being each supported at the center by a hollow wrought-iron column fixed to the floor plates. Four longitudinal beams, eighteen inches deep, also assist in stiffening the railway deck, these beams being placed immediately beneath the lines of rails.

The engines are of 200 horse power nominal, and consist of two independent pairs arranged one on each side of the vessel, in the spaces which are divided from the central part of the longitudinal bulkheads. Each pair of engines consists of two oscillating cylinders inclined so as to form an angle of 90 degrees with each other, these cylinders being three feet four inches in diameter with six feet stroke. The centers of the cylinders are in line, the two piston rods being coupled to one crank pin. The engines are fitted with the link motion for reversing, and are also provided with separate expansion gear. The cranks are overhung, there being one frame in each engine-room supported by a pair of columns, while the outer ends of the shafts are carried by the paddle beams. The paddle wheels are twenty-four feet in diameter, and have each twenty-four fixed floats; and as each wheel its driven by its independent pair of engines the two wheels can be run in opposite directions to facilitate turning the vessel if required.

In the space between the two pairs of engines is placed an auxiliary engine which drives one of Gwynne's centrifugal pumps, and also the four capstans of the ship. There are four boilers, two to each pair of engines, and they are placed close to the sides of the vessel, the one pair forward and and the other pair aft of the engines to which they respectively belong. The coal bunkers are also placed close to the sides of the vessel, the one forward and the other aft of the engines, each bunker being thus on the opposite side of the ship to the boiler which it supplies. By the arrangement of boilers above described, the funnels are brought to the sides of the vessel clear of the railway trains. The boilers are worked at a pressure of twenty-eight pounds per square inch.

As the water level in Lake Constance varies somewhat at different seasons, and as the vessel is of course liable to fluctuations of load, it may be required on some occasions to lower either end of the vessel to facilitate the embarkation or debarkation of the wagons. For this purpose the compartments between the two extreme bulkheads at each end are not only made watertight but are well stayed, so that they serve as water holds. Cocks and pipes connected with the pumps driven by the auxiliary engine enable these compartments to be filled with water and emptied at pleasure; and by filling one of them more or less, the end of the vessel to which it belongs can be sunk as required.

The designs and specifications for the ferry boat we have described, were prepared by Mr. J. Scott Russell, who is the engineer to the undertaking. The boat and engines were built by Messrs. Escher, Wyss & Co., of Zurich, the engines being designed by Mr. Murray Jackson, who was at the time manager to the above mentioned firm, but who is now engineer-in-chief to the Danube Imperial and Royal Steam Navigation Company. From some delay which has occurred, the ferry has not yet commenced running, but it is expected to start soon, and there is no doubt that it will be a success.

HEAVY RAILS.—The plan of Mr. Brunlees, for the new railway from London to Brighton (although it is to be a "cheap" railway, involves the use of steel rails of over 100 lb. to the yard, so as to have a head of the width of the tread of the wheels, and to distribute the weight of the rolling stock so as to obtain less than the present weight per wheel, and thus preserve the way.

TRACTION ENGINES IN FRANCE.

RESULTS OF EXPERIMENTS — THE ENGINES IN THE EXPOSITION. BY MONS. D. SIENARD.

Translated from "Annales du Génie Civil."

The problem of steam traction on common roads has been considered for a long time, even before the invention of railways; but not until within a few years has it begun to receive a practical solution. The road locomotive seems naturally called to fill the interval necessarily left in our system of railways; and it also offers important resources to certain industries which, like the beet sugar manufacture in particular, require much local transportation. It is, therefore, a question wholly practical; and although I am not prepared to treat it fully, I think it will be interesting to state the result of experiments which I have had occasion to follow up in the department de l'Aisne, on two road locomotives, the one of English manufacture, the other from the works of Mons. Albaret of Liancourt.

Mons. Albaret, in the arrangement of his machine, has not departed widely from the type of the railway locomotive. The boiler is composed of a cylindrical fire-box, and a horizontal barrel traversed by tubes, and is fed by a Giffard injector; and the heating surface is about 172 square feet. As the engine is to go on steep grades, it was necessary to provide against the inconveniences of changes in the water level. This difficulty has been happily solved. The horizontal barrel is full of water; and the steam formed in it while going up hill is received in a small dome on the forward end, and carried thence by an exterior pipe to the main dome over the fire-box; and the crown-sheet of the fire-box, instead of being flat, is hemispherical, and therefore always covered by an equal depth of water, whatever the inclination of the road.

The motive apparatus is composed of two cylinders, with link-valve gear placed under the boiler, and protected from dust by sheet-iron coverings, easily removed for oiling and cleaning. The crank-shaft transmits the motion by gearing to an intermediate shaft close in front of the fire-box, and on a level with the driving axle; and from this shaft the power is transmitted by an endless chain to the axle which is behind the fire-box. The driving wheels can be loosened or fixed to the axle by bolts, but not without stopping the engine. I do not know whether others have, in a practical manner, fastened and loosened the wheels while in motion; but this is one of the points which ought to have the attention of mechanicians. The machine cannot turn conveniently without one wheel loose; and so long as the fixing and loosing cannot be effected while in motion, it will be almost necessary to work with one wheel loose, thus using only half the force which the machine might exert.

Road locomotives not being guided by rails, it is necessary that their front axles should be turned to the right or left. It is in this part that they differ most from each other. In the arrangement of Mons. Albaret, the front axle wheels are in advance of the smoke-box. To the middle of the axle is jointed an upright spindle, which turns in a socket that is held by a prolongation of the upper part of the smoke-box—the prolongation being high enough to allow the wheels 54 inches high, to turn under it, like the wheels of a common coach. The spindle is worked by an endless screw turned by a hand crank, gearing into a worm wheel on the upper end of the spindle. The shaft of the screw is prolonged to the foot-plate, so that the engineman can steer; and in this respect it has an advantage over other engines, which require special men to steer. This arrangement is important; because, independently of the saving of the wages of a steersman, it renders the maneuvering much more easy and certain. The machine is mounted on springs to soften the effects of jarring and jolting. In front there is a conical spiral spring around the spindle; and the hind springs are of the common laminated kind. The total weight is about ten tons, of which six and a half are on the drivers, which are five feet high and fourteen inches wide at the rims. The usual speed is five kilometres an hour, and the highest speed allowed is seven kilometres, (about three and one-third and four and one-third miles).

After being exhibited at the competition at Laon, in 1866, this engine was bought by Mons. Godin-Lemaire, to draw coal and iron for his foundry at Guise (Aisne). It worked between Guise and the fort of Longchamps a distance of four kilometres (two and two-third miles). It went out lightly loaded, and returned with a useful load of 15,000 kilogrammes (about fifteen tons), and burns at the maximum 250 kilos (550 lbs.), of coal per round trip. At these rates the daily expenses are less than half the cost of horse power.

Mons. Godin-Lemaire is, nevertheless, little satisfied with the results of his experiment—for it is not enough that the current expenses be reduced; it is necessary moreover that the machine shall be exempt from frequent derangements and important repairs. Unfortunately this locomotive leaves something to be desired in this respect. In the first place there have been and still occur, numerous leaks at the tube joints. These may be due to bad original construction; but it is to be feared that the suspension of the boiler is not without influence in this evil. The boiler is suspended at its ends, the axles nearly fourteen feet apart, and the jolts may cause strains very prejudicial to the joints. In the second place, the endless chains that transmit the power from the intermediate shaft to the driving axle have been found too weak; and the links and the teeth of the pinions have been much worn, and there have been many ruptures of them. Moreover the chains have been elongated—and not being sufficiently guided they have sometimes got outside the teeth, under the effects of violent lurches. Attempts have been made to mitigate the effects of the lengthening of the chain, by applying a tension rod, and making the pillow blocks of the intermediate shaft adjustable; but it is clear that the most efficacious remedy would be in the use of a chain so strong that the elongation would be insignificant; for, in spite of the two expedients above stated, there was produced such a difference between the relative pitch of the chain and the wheels, that they could not work together without a series of small shocks.

However these points may be, Mons. Godin-Lemaire seems convinced that the transmission by chain is, in itself, bad; and that the road locomotive cannot become really practicable and capable of regular service, until the chain is superseded. I do not know whether the future will confirm this opinion; but I will remark that the experiments have been made under disadvantages, as Mons. Godin-Lemaire himself was the first to point out. In fact, the Longchamps route, which leads also to Bohain, is the one on which is performed nearly all the traffic of the industrial establishments of Guise. It is extremely worn, even to such extent that the merchandise brought from the north by railway has to be loaded at St. Quentin instead of Bohain. From this fact it will be understood that the route is very ill prepared to receive the road locomotive; that the machine was exposed to numerous chances of accident which it would not have met in ordinary practice; and that we cannot accept as definite the condemnation of a system, on the results of an experiment made under such unfavorable conditions.

The other experiment, of which I shall now speak, has given more satisfactory results. Mr. Pilter, an English mechanician, instead of copying the railway locomotive, has limited himself to adopting an ordinary portable engine, and establishing a connection between the crank-shaft and the driving axle, by means of an intermediate shaft and an endless chain, as in the French engine. The engine is placed on the boiler; the fly-wheel is retained; and by ungearing the intermediate shaft, the locomotive may be made to work as a portable engine. It is therefore particularly convenient for agriculturists. The boiler is a plain cylinder and fire-box, without dome, and has 203 feet of heating surface. No special precaution has been taken to prevent changes of the water level on hills; and only a fusible plug is put in the crown-sheet, to cause the fire to be extinguished by a jet of steam in case the crown-sheet should become dry and hot. It is fed by a pump which can be worked while the engine is standing, by ungearing the intermediate shaft. The driving-wheels are 64 inches in diameter, and sixteen inches width of rim. As in Albaret's engine, they are fastened and loosened by bolts; but in the French machine the fastening is possible in any position in which the engine can stop; while in the English it is necessary to bring the wheels to one position on the axle, so that the holes may be in line. The front swivelling train is very complex. It has three wheels; the hind axle under the fire-box, held to it by a swiveling joint. The steersman sits with his back to the smoke-box, and by a tiller turns the front wheel as it is turned in toy carriages. The system works perfectly in forward motion; but in maneuvering and in untrained hands there is likely to be a misunderstanding between the engineman and the steersman which may involve much loss of time, if not more serious consequences. The total weight, and the distribution of it on the axles, is about the same as in the French engine—and the ordinary speed is the same, three and one-third miles an hour.

This is the engine which, in October, '67, made the experiments of towing boats on the Oise, of which all the journals have spoken. It was thence taken to the sugar manufactory at Braisners, near Soissons, where Mons. Duffié proposed to use it for the transportation of beets. It worked for about 40 days between the factory and a depot at Cuiry-Housse, eight kilometres distant. The road is in very good condition, but its profile was very accidental, for it has barely two kilometres of level, and the rest is in steep hills and inclines varying from three to seven in 100. Its ordinary train was two large wagons, each containing 7.4 tons of beets. On the return trip it drew five to six tons of pulp. It made two round trips per day, and burnt 1,540 to 1,760 lbs. of coal. In going and returning the tank was filled with water by means of hose from a pond six kilometres from the factory; and in addition, to provide for emergencies, the train was always followed by a cask on a cart containing from two to three hectolitres of water. In dry weather the traction was easy, but in wet and muddy weather there was such slipping as to show the necessity of lightening the loads or roughening the wheels. Notwithstanding the regulations against rough wheels, the administration, fôr the sake of rendering the experiment conclusive in all respects, made no opposition, and Mons. Duffié applied on the tires of the driving wheels strips of plate iron 1.2 inches wide by 0.4 inches thick and 24 inches apart (eight on the entire circumference). With this addition the machine drew its load over the hills, and was no farther hindered in its work until the time of ice and fresh snow.

The service of this machine was generally satisfactory during the winter of 1867–8. This is not to say that it always avoided accidents, and that there were no ameliorations to be desired. Far from it. As the fusible plug corroded, it had to be replaced every week, although it had never been left completely uncovered. The chain, though stronger than that of Albaret, has had several links broken, and at the end of the season it had to be replaced. There have been some ruptures of teeth; and, at the outset, before the men had become expert, the complication of the swivelling train or three-wheel bogie occasioned some accidents during its maneuvers, such as getting into the ditches of the road, from which the machine could not always extricate itself. But these are accidents inevitable in the beginning of a new system, and Mons. Duffié, recognizing that his apparatus is far from having attained its ultimate perfection, does not hesitate to regard this machine, even in its present state, as capable of practical use, and of rendering important service to industry.

We will say a few words about cost.

Mons. Duffié generally sent four men with his convoy—three on the engine and one behind to look out for the train and hold the horses that were met, and aid the measurers at the beet depot. The wages of these men was 13 francs per day. The coal cost 21 francs (at 28 fr. per ton), and the oil cost four francs. In all, 38 francs per day to transport 40 tons of beets or pulp eight kilometres. The cost of haulage therefore amounted to .119 fr. per ton per kilometre. As to the general expenses, they are difficult to estimate, for they depend on the number of days of work in the year and the importance of the repairs of the machine. Mons. Duffié hopes to use the engine 100 days in the year, 50 in winter for transporting beets, and 50 in summer for supplying coal and for working in cultivation. The engine cost 14,000 francs, and six wagons at 1,000 francs each, makes 20,000 francs for the cost of his material. Allowing 20 per cent for interest and decay, the engine being estimated to last six years, and adding 1,000 francs per year for repairs, we have a yearly expense of 5,000 francs, which distributed over the work of the 100 days gives .156 francs per ton per kilometre. The total cost, therefore, is .275 francs. At this rate, Mons. Duffié has already realized some economy, for the transport of beets by the wagoners has never cost him less than .3 francs, and it has often cost more in unfavorable seasons.

These costs have been very largely estimated, and in many cases they may be much reduced. The consumption of coal has been enormous, nearly 24 kilogrammes per kilometre, which is just twice what the constructors state in their advertisements, but without reckoning the lighting of the fires. This excess arises from two causes. First, from the profile of the road, whose grades considerably augment the resistance to traction. Second, the season in which the work was done, for the resistance to rolling varies much in consequence of the dryness or wetness of the road. When the road was frozen they have been able to make three round trips in a day, and then the consumption of coal did not exceed 950 kilogrammes; that is, less than 20 kilogrammes per kilometre. We may therefore admit that in a fine season, and on a route with good grades, the consumption would not exceed sixteen or eighteen kilogrammes, and the price would then be lowered .02 per ton per kilometre. Besides, I have supposed only 100 days' work in a year, while the machine could easily work 250 days and leave time enough for cleaning and repairs. Computing in this case the decay at 30 per cent and the repairs at 1,500 francs, the general cost would be lessened at least one franc per ton per kilometre. Finally, Mons. Duffié's engine worked but 32 kilometres daily, when it could have worked 40 or more, and, in effect, it did but a third of the work of which it was capable. I think, then, that it may be concluded, from the experiments at Braisne, that in the present state of the engines they can transport at .2 francs per ton per kilometre, provided they have work enough to keep them fully employed, and to attain this result it will suffice to have 400 tons of transportation to do during 250 days in the year. This amount of work could, at the most, supply a railway only two kilometres long.

In what precedes I have occupied myself only with the machines. I have endeavored to show the results already attained and to indicate the improvements which had to be realized. I cannot pretend to have succeeded fully, since I have had occasion to examine only two types of road engine, both exclusively for freight. But in the organization of a system of steam traction it is necessary also to think of the embarrassment of the travel already existing on the roads and of the effect of the new system on the preservation of the roads. In these relations the experiments at Guise and Braisne are conclusive. The locomotive obeys with the greatest docility the direction of its conductor, and easily makes way for other vehicles to pass; but, owing to its great weight, it does not always do this without danger to itself, when the roads are narrow and the sidings are very soft. In such case it cannot always cede half the road, as required by regulations, without difficulty to itself. Horses soon accustom themselves to the noise of the machine, and after a few trips they pass without more alarm than they show in passing common vehicles. Still, with pleasure horses that are more spirited than work horses, precautions are taken; but these horses are not frequently met.

Finally, the locomotives, with their broad wheels, heavily loaded, serve as road rollers, and seem to have only good effects on macadam. The front wheels being nearer together than the drivers, a considerable part of the road is rolled and there is no tendency to form ruts. At Guise, as at Braisne, it was remarked that the road was injured only by the wagons, whose wheels were not wide in proportion to their loads. It will be easy to build wagons with wider wheels and the front wheels nearer together than the hind wheels as in the locomotives, so that the steam trains may have the best effect on roads.

By the regulations made for road locomotives, their tires must be smooth, without any projection. It was feared that if otherwise, they might break up the surface and seriously impair the durability of roads. But the trial of Mons. Duffié showed that these fears were unfounded. I was at Brisne after several days of rain. On the road there were some parts dry, others moist and soft, and others covered with mud. On the dry parts the holding strips left slight traces; on the soft parts there were mere impressions of the strips; and only in the mud, where the foot would leave a track, was there any tearing up; and this did not extend below the stratum of mud nor affect the macadamising. And even this slightly injurious effect would not have been produced had the strips been put near together, instead of two feet apart. With this distance apart it often happened that no strip had held, and there was slipping, and the next strip arrived at considerable speed, striking a blow which tore up the ground. Yet at the end of the year this road was not more worn than at the end of previous years, and Mons. Duffié had no increased road taxes to pay. And I am persuaded that the interdiction of holding strips will be removed, since they are allowed in England, where road engines have come much into use. I will add that, in my opinion, this is a condition indispensable to the general use of steam traction, for the load that can be drawn with smooth tires is too limited, the force of the machine not well utilised, the dead weight too considerable, and the transportation cannot be performed with full economy. And were it true, which I think is not, that the projecting strips injured the roads, their use should nevertheless be permitted; for the State and the Departments, in providing for the repairs, would only have to lay just taxes on the new engines, which they could pay, and still work with advantage.

The Exhibition of '67 in the Champ de Mars brought together nine road locomotives, from four French and five English construetors. The English seem not to have thought seriously of applying them to the transportation of passengers, for their machines are adapted to draw heavy loads at relatively low speed—seven or eight kilometres at most. But in France the inventors have schemed to carry both passeners and goods. The locomotive of Mons. Larmanjat can draw only three tons, but its speed is sixteen to eighteen kilometres per hour, which is practicable only for passengers. Mons. Lotz, of Nantes, has aimed to construct a machine suitable for both services. The other French constructors, like the English, propose to carry only merchandise.

Before examining each machine particularly, I will glance at the whole together, to set forth the general characteristics adopted by their constructors.

Boilers.—Besides the conditions common to all boilers, there are two specially necessary to be considered in boilers for road locomotives. First, they must be made so that the fire-box crown-sheets shall remain covered with water while going up hills. Second, the form of the boiler should permit a firm and accessible arrangement of the organs of motion. The English have all adopted the same kind of boiler—the locomotive without a steam dome. This allows great latitude in the arrangement of the engines, on top or underneath. The danger of burning the crown-sheet is guarded against by a fusible plug, which will melt and allow steam to extinguish the fire before an explosion can occur. This system is simple, but it cuts the knot rather than unties it, and it may have the inconvenience of supplying moist steam, for want of a high and copious reservoir.

The French have been more inventive. The design of Mons. Albaret we have described. That of Mons. Larmanjat is analogous to it. Mons. Calla's has also a dome over the fire-box and a barrel long enough to accommodate the motive mechanism. But the most radical solution is given by Mons. Lotz, who completely separates the boiler from the engines. The boiler is upright and behind the driving axle, and the engine is inverted and attached to the tank, which is placed forward at the distance suitable for the gearing and chain. The two conditions which I have stated are perfectly fulfilled, but it is to be feared that the boiler will be found too small for the speed proposed. On the whole, I think the English type is really the most practical.

MOTIVE MECHANISM.—The first question is, whether there should be one or two cylinders. With two the motion is more equable, and there are no dead points. With one the construction is cheaper, and the maximum effort greater. This last advantage is not to be disdained in a machine which is liable to get mired, and to require for a moment a strong exertion of force. On this question opinions are divided, and of the nine engines, four (three of which are French), have two cylinders. The English have all put their cylinders on top of the boiler, near the chimney. Calla has put his cylinders on top, but near the fire-box. Albaret and Larmanjat place theirs under the boiler, where the mechanism is least accessible and most exposed to dust; but they have endeavored to exclude dust by coverings. And Lotz has placed his cylinder vertically over its shaft, in the forward part of the vehicle. This disposition is perhaps objectionable on account of the disturbance by the up-and-down movement of the piston.

MODE OF TRANSMISSION OF THE MOTION.—I have already spoken of the inconveniences of chains for transmitting motion from the intermediate shaft to the driving-wheels. Nevertheless, there are but three English constructors who have completely abandoned that system. Whatever be the mode of transmission, nearly all the machines can vary the number of turns of the engine to one turn of the wheels. Those of Albaret and Pilter are the exceptions. The others, excepting Lotz and Larmanjat, who aim to carry passengers, in their devices to vary the speed, have no other object than to save time when going without loads. All the French engines are on springs, and this is evidently advantageous on account of durability; but none of the English have deemed it useful to adopt this refinement. All the French engines have smooth driving-wheels, as required by the regulations. The English restrict themselves to this condition only in engines which they hope to sell in France.

STEERING APPARATUS.—For the swivelling of the front axle or truck there are as many plans as there are constructors. Of the nine machines five are steered by a special conductor placed in front; the four others are steered by the engineman. In going forward the first system evidently gives most safety; and it appears to me best for passenger carriages; but it is more costly, and renders maneuvering more complex, in consequence of want of perfect understanding between the engineman and steersman. I now pass to the examination of the different models separately, commencing with the English.

PILTER'S ENGINE.—Having shown the general arrangement of this machine, I shall here consider only some details of construction. The intermediate shaft, between the crank-shaft and the driving axle, is not placed high enough to pass over the top of the boiler; it therefore has but one bearing, and its working end overhangs. This disposition is unsatisfactory, and it is not surprising that several ruptures of the pillow-block occurred on the machine belonging to Mons. Duffié. On Pilter's locomotive, in the Exhibition, the motion is transmitted by wheels with conical surfaces, which work against each other, depending on friction. This system has the advantage of easy connection and disconnection while in motion; but it may be questioned whether, in practice, this kind of frictional gearing will have sufficient adhesion.

AVELING & PORTER'S MACHINE.—This has the same disposition as that of Pilter's, which is but a copy of it; for Aveling invented the three-wheel truck.* The intermediate shaft is not over-hung, as in Pilter's, but is placed high enough to pass over the boiler, and have a bearing each side. This shaft and the crank-shaft carry gear wheels at both ends, with different proportions, so that the speed may be varied by throwing either the right or left into gear. As in Mons. Duffié's machine, the fixing of the wheels is by bolts. Experience proves that when the tires are smooth, the fixing can be effected very well while in motion When one wheel is fixed and the other loose, the former slips a little, and soon brings the holes into line, so that the bolt can be pushed home; and this happens the sooner when the slipping is greatest, and there is

* We translate without comment. Our readers may know that this is older than Aveling; and on other points they may see that we might have corrected the author; but we deem it best to reserve our criticisms until we have occasion to write an original article on this subject.

most need of the adhesion of both wheels. The loosening is not practicable without stopping, for the bolt is held too strongly to be withdrawn while the power is exerted upon it. Porter's steering gear certainly requires the least effort of the steersman of any that I have seen. In maneuvering it requires a certain degree of expertness; but even in this view it is not inferior to the other systems that require a special steersman. Messrs. Aveling & Porter had two locomotives in the Exhibition, for which they received a medal. One, of six horse power, was bought by Mons. Schotman, of Don, to tow boats on canals. The other was of twelve horse power. They have engines now at work at the sugar factories in Nesles (Somme), in Barbiere (Oise), and in Moncornet (Aisne).

Machine of Clayton, Shuttleworth & Co. (Medal of the Exhibition)—It has two cylinders under the boiler. The transmission of the motion is by spur-gearing on two intermediate shafts; one of them over-hanging, like Pilter's. They say, in their prospectus, that their engine can turn curves of the shortest radius, being enabled by differential gearing of their own invention. I could not see this mechanism, as the attendant of their machine covered it when he saw that I was studying it closely. It has two steering wheels and a steersman in front.

Ransome's Machine.—This has one cylinder on the boiler near the chimney. The motion is transmitted by spur-gearing on two intermediate shafts, one of which is used only for slow motion. The fixing of the wheels is by friction clutches; but it is not effected while in motion. It has two steering wheels, and the smoke-box rests on the centre of the axle. Chains go from the ends of the axle to a horizontal wheel behind the engineman, who steers.

Underhill's Machine.—This has one cylinder. The motion is transmitted by spur-gearing. The fixing of the wheels is by bolts, as in Pilter's. It has two steering-wheels, with the load on the middle of the axle, as in Ransome's. A strong rod, jointed to one end of the axle, goes to the foot plate, where it is formed into a rack, and pushed or pulled by a pinion worked by the engineman. What strikes us in this machine is the extraordinary form of the driving-wheels, whose rims are of wood, with iron tires zigzagged, so as to leave on the ground a track similar to one represented by the figure 6. This system may give adhesion; but it may be feared that it will fail to give strength. For the rest, the constructors seem to have aimed to make portable engines that could propel themselves from place to place, rather than traction engines, for they have not provided coal boxes.

Larmanjat's Machine. (Medal of the Exhibition.)—It is of three horse-power, and expressly for passengers, and can draw three tons. Its centre of gravity is very low, which gives it great stability. It has two cylinders under the smoke-box turning a crank-shaft under the fire-box. This shaft acts by gearing on the driving axle. Behind the driving axle is a shorter axle, with smaller wheels, and an endless chain transmits the motion from one axle to the other. By levers, worked by screws, the smaller wheels may be made to carry the load, or may be lifted clear of the ground,—the wheels that are not carrying continuing to turn. When on a level the large wheels carry and run at sixteen to eighteen kilometres an hour; and on hills the small wheels carry at seven to eight kilometres. The higher speed is ten to eleven and a quarter, and the lower is four and three-eights to five miles per hour. This combination seems capable of working well; but evidently it is inapplicable to a heavy engine, and could not be used for a locomotive that draws heavy loads. It is steered by one wheel, held by a forked spindle, on the top of which is an arm, to which is jointed a rod worked by a pinion, by the engineman.

Lotz's Machine.—In external appearance this machine differs entirely from the others, which all more or less resemble railway locomotives or portable engines. In this all the organs are placed on a sheet-iron body with three wheels. Behind the driving axle is an upright boiler, and in front is the engine. The cylinder is vertical. The crank-shaft and two intermediate shafts are on a level with the platform. The motion is transmitted to the drivers by an endless chain. Gearings of different proportions, with clutches, enable the machine to be worked at three rates of speed. This complete separation of the boiler from the machinery has the great advantage of rendering repairs easy; and the engineman has all parts in sight and accessible. But, as I have said, the boiler appears too small. The driving axle has springs and axle boxes like those on railways. The fixing of the wheels is by a brake, analogous to that in Ransome's. The axle of the steering wheel is fixed in a horizontal wheel with teeth on its rim, into which a pinion works, and a special steersman works the pinion. Lotz's engine has been bought by the director of the glass-works of Folembray (Aisne), and has worked since November, 1867, between Coucy and Chauny, transporting materials and products. Several other similar machines work at Orleans and at the mines of Blanzy.

ALBARET'S MACHINE.—Save, in a few details, Albaret's machine in the Exhibition is like the one we have reported. The endless chains are made stronger; and this is the only one that has a chain to each driving wheel.

COLLA'S MACHINE.—It has a framing like a locomotive, formed of two long plates with proper connections. This is an improvement; for it bears the shocks and strains which in the English and Albaret's engines are thrown upon the boiler. It has a steam dome over the fire-box, and a barrel long enough to receive the engines. The cylinders are on top, near the fire-box, and the crank shaft forward, and the intermediate shaft further forward, close to the chimney. With this arrangement the endless chain has to be very long, though the driving axle is before the fire-box; and the lengthening of the chain must therefore be more sensible. There are two steering wheels in front of the smoke-box, under the frame plates. The axle is connected to a horizontal wheel with a toothed rim, into which a pinion gears; and the pinion is turned by a band wheel worked by a special steersman. The drivers are fixed and loosened by clutches, which are worked while the engine is in motion. In the other engines the steersman in front has only to steer. In this he has to work the clutches which fix the wheels, and also to work the levers which change the rates of speed. The engineman has charge of the throttle, the reversing lever and the fire. Experience only can show whether this division of functions, between men so far apart, is the most advantageous. Under the seat of the conductor is a shaft worked by a chain, which in case of accident will serve to warp the machine forward, by winding a chain or rope that is fastened to an anchor or other fixed object ahead. This engine is solidly built; all its parts have been well studied; and all the difficulties have been noticed. But there is another side: on account of the steam dome the boiler has been made long to give room for the mechanism. The necessary organs are numerous, and augment the weight; and as the division of the weight between the axles is very unequal, because of the driving axle being before the fire-box, the weight on the drivers is excessive, twelve tons at least. This weight far exceeds the regulations; and there are few routes on which such a heavy engine could work safely.

I conclude this rapid review by saying that I entirely agree with the international jury who awarded the first premium to Messrs. Aveling & Porter. Their machine is the one which, by its simplicity and good construction, seems for the present to offer the best assurance of efficient and regular service on common roads.

ENGINEERING IN INDIA.—From a comprehensive article in the Calcutta "Engineers' Journal," we learn that the Government has fully sanctioned the establishment of the best schemes of irrigation and navigation throughout this vast industrial empire. Among the schemes for irrigation, surveyed and to be commenced, are the construction of 16 reservoirs in the Midnapore district, from which some 75,000 acres of land may be watered; also a canal for navigation and irrigation, from the Damoodah to Calcutta, 100 miles (already commenced); a system of canals from the Gunduck for the benefit of the districts of Chumparan, Sarun, and Tirhoot, and a canal from the Ganges at Rajmahal to Calcutta, also the Sutlej canal in Punjab—all these canals being designed to prevent the horrors of famine heretofore prevalent, and being adapted to navigation.

An Imperial sanitary commission has been appointed. One of its chief duties is to detect the cause of disease as arising from drainage, water supply, and ventilation. Simultaneously with this office the Government of India has made the appointment of an experienced mining engineer in connection with the geological survey of India, for the purpose of determining with precision the mineral resources of India, improving and extending mining operations, and subsequently collecting and tabulating the mineral statistics of the country, which has been looked upon with great pleasure and satisfaction by the country at large.

THE "UNIVERSAL" ROLLING MILL.

In an article on the progress of the British iron trade, "The Engineer" says: There is no one practically connected with the iron trade who is not tolerably familiar with what, by the use of the universal mill, Messrs. Petin, Gaudet & Co., for example (in France), have been able to accomplish. Their famous rolled beam 39⅜ inches in depth, exceeding 32 feet, in length, and weighing two and a half tons, with also their more than two-ton beam, upwards of a foot in height, and above 106 feet in length, in the Paris Exposition, evidenced the capabilities of the the universal mill.

The mill, as laid down at Messrs. Petin, Gaudet & Co.'s works, is not remarkable for novelty, for its essential features are to be found elsewhere, and Mr. Abram S. Hewett claims that they were embraced in the first train for rolling beams erected in 1853 at the Trenton works, New Jersey. Whilst the universal mill is by no means unknown to many of our readers, they may nevertheless feel interested in reading the description of it as given by the intelligent American ironmaster and United States commissioner we have named. He says that "for each size of beam there is a pair of rolls, each having a working face at the middle of its length equal in width to the depth of the beam. The diameter of the roll at this part is very large, say three feet six inches, the body of the roll for the rest of its length being about 22 inches in diameter. This formation of the rolls leaves a considerable space between the two, except where the working faces come together. In this open space is placed a pair of rollers working on vertical axes fixed in stout movable frames, by which they can be brought into juxtaposition with that portion of the horizontal rolls which is of largest diameter. The pile used is somewhat thinner than the width of the flange to be produced, and of a width somewhat greater than the depth of the beam, and is so made up as to conform roughly to the final shape of the girder. As the main rolls are brought together and form the trough in the beam, the friction rollers at the sides are also pressed towards the centre, and tend by the pressure which they exert to extend the flanges at the same time that the web is being drawn out by the main rolls. An offset is turned in the side of the large portion of the rolls to receive and form properly the flange as it is extended by the pressure of the friction rolls. The latter are worked each by a screw in a horizontal frame bolted to the side of the housing, the screw being provided with a ratchet lever to be worked by hand. This enables the thickness of the flanges to be adjusted with precision. With this mill Messrs. Petin, Gaudet & Co. have rolled girders of 40 inch high, 33 feet long, and feel confident they could make them 90 feet in length." We have said that the essential features of this mill were applied in the United States, more than fifteen years ago, but in the mill at Trenton the axes of the driver rolls and of the friction rolls were at right angles to the mill of Petin, Gaudet & Co. That the latter is a better working arrangement than the former there can scarcely be any doubt.

It is no argument against the universal mill that the immense products exhibited in Paris as resulting from its operation are mere *tours de force*. No doubt a careful observation of the various structures in process of erection on the continent would fail show that these remarkable specimens of rolling have yet been brought within such limits of cost as to admit of their use in building. We know that in the Exposition building itself, no rolled beams were to be found of a greater depth than nine inches; and it is a fact that in the very many structures which are now being put up in the capital of France in which iron beams are invariably employed to the exclusion of wood, four-inch, six-inch and seven-inch are the dimensions most generally employed. But now that it has been found possible to produce beams of such large dimensions by the simple process of rolling, Mr. Hewett himself observes, "it is but reasonable to expect that the cost will be reduced as experience is gained, and that the large single girders will gradually replace the riveted girders, which even in the palace of the Louvre are invariably employed for spans of any considerable extent."

The universal mill had its origin in this country, but it came out at a time when its importance was not correctly estimated here; nor, so far as it relates to beams of the class we have been writing about, would its application have been of much value in England at this time. Now the mill is getting into use. The most recent train of this kind is intended for rolling long narrow plates without the necessity of their being afterwards sheared.

STRESS DIAGRAMS FOR STRAIGHT RAFTER ROOFS.

In a former article* we explained how the stresses in a Warren girder can be determined by means of a simple and easily constructed diagram. We will now proceed to determine the stresses in some of the commoner kinds of iron roofs—such as are indicated in figs. 1 and 3. In the form most commonly used in England, fig. 1 represents a roof with four bays to each half. The first step is to determine the load which produces the most unfavorable stresses in the different bars. In general, this load is not the same for all the bars; but in the present case, in which the top and bottom beams A C and A J are straight and meet at the end points A and B, the greatest load possible uniformly distributed over the whole rafter gives the greatest stresses in all the bars. We have, therefore, to consider this load only. It consists, first, in the dead weight of the girder; second, the weight of the covering; third, in the greatest possible load of snow which may fall on the roof; fourth, the maximum pressure of the wind. The girder ought to be loaded at the connecting points only—that is to say, at the points A D E F C, &c., for otherwise the bars of the top beam would have to sustain bending forces requiring more material than for mere tension or compression. We, therefore, suppose that the covering rests on the girder only at these points. When one of these points, E, for instance, is loaded with the weight upon half the bay D E and upon half the bay E F, or when the top beam is divided into equal portions, the load upon one connecting point is equal to the load upon a rectangular superficies extending in length from one rafter to another, and extending in breadth from one connecting point of this rafter to the next. The weight resting upon the points A and B does not affect the construction, as these are directly taken up by the support. Let us now suppose the weight on each connecting point to be two tons. Then the whole load on the girder is 7 by 2, or 14 tons. As this is symmetrically distributed with regard to the two supports A and B, each of these has to take 7 tons. These data are sufficient to determine the stresses, and we will begin to construct the diagram of forces.

We employ in this instance a mode of denoting the bars and forces which is much more convenient than that used in the former article. Structures to which the graphical method is applicable consist of bars forming a number of triangles, and we accordingly write in each of these triangles a figure, successively numbering these triangles in their natural order. In figs. 1 and 3, this is done by the numerals 5, 6, 7, 8, 9, 10 and 11. Opposite each top and bottom bar other figures are placed, and it will be observed that for all the bottom bars the figure 0 is used, whilst the bars in the top plane have different numerals, 1 2 3 4. This difference is due to the fact that the bottom is not loaded. If one of the connecting points at the bottom—for instance the point C in fig. 1—were loaded, we should be obliged to use, to the right and left of the load at C, different numerals. In this way each bar has at each of its sides a figure by which it is clearly indicated. The top bar, E F in fig. 1, is thus denoted by 2 8, whilst 6 7 denotes the bar E G. Similarly the load at point E may be denoted by 2 3. This mode of marking the bars will, perhaps, appear at first rather strange and arbitrary; but we shall see further on that it greatly simplifies the indication of the forces in the diagram of stresses and the correspondence between the two figures.

The process of constructing the diagram of forces for this roof is exactly the same as in the former case of a Warren girder. We begin at the point A, where the known resistance of the support acts with a force of 7 tons. This we have to decompose into two components with the directions of the bars 4 5 and 5 0. Draw a line 0 4 (in fig. 2) parallel to the force A in fig. 1, and therefore vertical, make its length to any scale, equal to A, or, in our case, equal to 7 tons. Through the two end points 0 and 4 draw lines parallel to the directions of the bars 0 5 4 5, and let these lines meet at the point 5. Then 0 5 and 4 5 in fig. 2, determine the forces respectively acting in these bars. To ascertain if these forces produce tension or compression we follow round the triangle 0 4 5 in the direction which is prescribed by the direction of the known force 0 4. We find that the force 4 5 acts from 5 to 4 and 0 5 from 0 to 5. In the girder, fig. 1, these forces act parallel; the force in 4 5 acts parallel to the direction from 5 to 4; or from D towards A in fig. 1. It, therefore, produces compression; similarly, the force in 0 5 acts in the direction from 0 to 5 in fig. 2; that is, from A to C in fig. 1, pro-

FIG. 1.

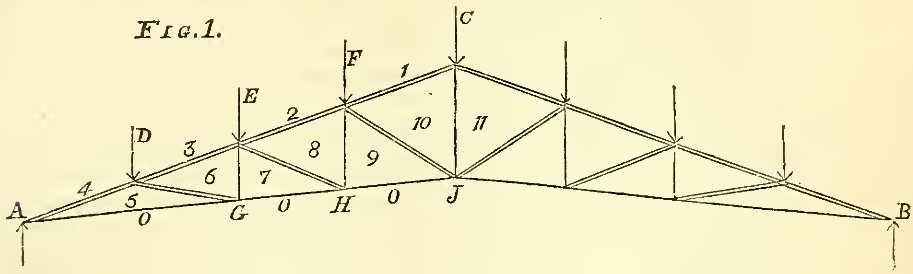

FIG. 2.

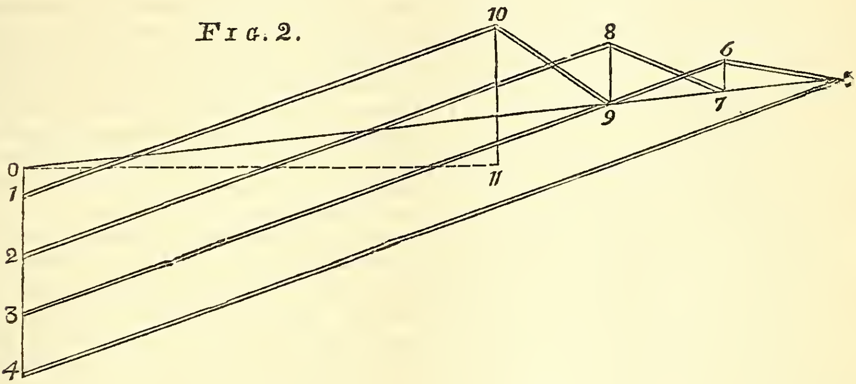

FIG. 3.

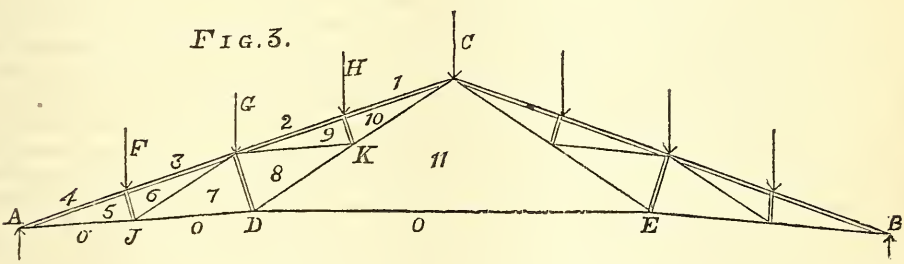

FIG. 4.

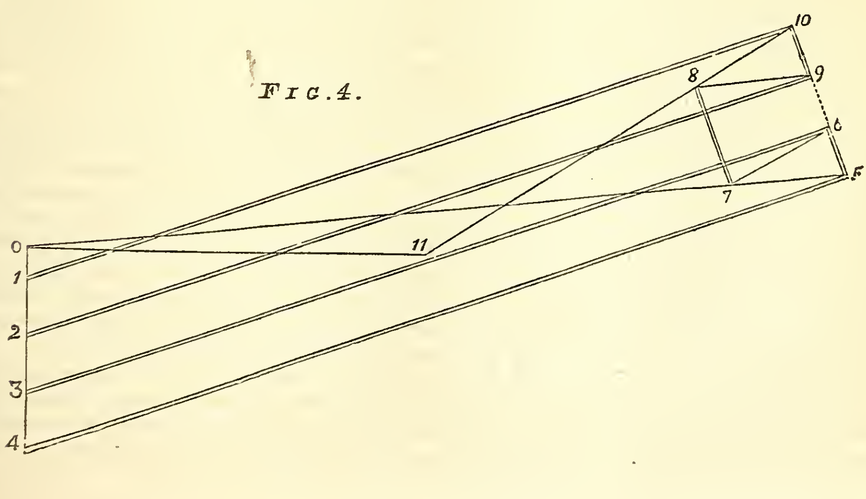

ducing tension. Compression is again denoted by a double line in both figures. We now go to the point D, where we have to combine 4 5 with the load 3 4 of two tons; and to decompose the resultant into the directions of 5 6 and 3 6. We remember that the compressed bar 4 5 presses at the point D in the direction from A to D; or, in this diagram of stresses, in the direction from 4 to 5. To this force 4 5 we add the load 3 4. The line adjoining 3 5 would give the resultant of the two known forces acting upon the point D. It is unnecessary to draw this line. We decompose this force with the given directions by drawing through the end and points 3 and 5 two lines parallel to our two bars 5 6 and 6 3 in fig. 1. Let 3 6 and 5 6 be these lines, which intersect at 6. Then 3 6 in fig. 2 is the stress acting on the bar 3 6 in fig. 1; and 5 6 that acting upon the bars 5 6. To find the direction of these forces we follow round the polygon 3 4 5 6 in the direction determined by the known forces 3 4 and 4 and 5, which are, as required, placed together in such wise that they travel the same direction by passing along these lines from 3 over 4 to 5. Proceeding, we pass from 5 to 6, and from 6 to 3. Hence the force 5 6 has in fig. 1 the direction G to D. It presses against the point D, and has, therefore, to sustain compression; and 3 6 has likewise compression. We next come to the point G, where 5 0 and 5 6 act as known stresses. They are represented in the diagram of stresses by the lines having the same figures and placed in the same way as they point in the direction 0 5 6. Drawing through the end points 6 and 0 lines parallel to the bars 6 7 and 7 0, we get the lines 6 7 and 7 0 as stresses in these two bars. They act in the direction from 7 to 6 and from 0 to 7; or in fig. 1 in the direction from G to E and from G to H, as we follow round the lines in the direction 6 5 0 7 6 0. Hence both bars are undergoing tension. In this case, the line 0 7 coincides in direction with 0 5, but by our present mode of notation an ambiguity is impossible. We thus continue, necessarily taking the points E H F J. Drawing from each point the corresponding lines in the diagram of stresses we obtain fig. 2.

This diagram determines all the stresses. Measuring all the lines with the same scale by which the first line 0 4 is made equal to 7 tons, we obtain the stresses directly. Only the stress 10 11 in the center tie-rod is not given at its proper amount. The line given in the diagram represents the tension down to only one-half of the rafter; but as this bar belongs equally to the second half, the stress, as taken from the diagram, is to be doubled.

Here, as in the case of a Warren girder, we have determined all stresses by expressing for each connecting point that the forces acting upon that point are in equilibrium. We began at one of the supports and proceeded by taking the other connecting points in their natural order till all the stresses were found. This process is always possible, unless it should happen that these forces are unknown at one point. This is not the case with the rafter, fig. 3, which illustrates a form of roofing much used in France and Belgium, and known in England under the name of the French roof. A diagram as simple as that in the former case enables one to determine all the stresses.

We again suppose the rafter, fig. 3, to be loaded at the connecting points F G H C, and so on for the other half, and with equal weights—say 2 tons at each point. The whole load will be 14 tons, half of which comes upon each support. This load of 7 tons we represent by the vertical line 0 4 in fig. 4, and divide it at the points 1 2 3 in such wise that 4 3, 3 2, 2 1, each represent 2 tons, corresponding to the loads at the points F G H. The remaining part 1 0 is then equal to half the load at C. Through the points 4 3 2 1 draw lines parallel to the top beam A C, and through 0 draw a line 0 5 parallel to the bottom beam A D, which cuts the lowest of the former lines at 5. Through this point 5 draw a line 5 10 parallel to the struts 5 6, 7 8, 9, 10, or at right angles to 4 5. This line determines the points 6 9 10, and the forces in the top beam by the lines 4 5, 3 6, 2 9 and 1 10. Lines drawn through 0 and 10 parallel to D E and D C meet at 11, and determine the stresses 0 11 in the great tie rod D E, and in the bar 10 11. To complete the diagram it only remains to draw 9 8 and 6 7 parallel to the corresponding bars in the elevation, fig. 3, and to join 7 8. Having done this, all stresses are determined, and the figures at once show which line in the diagram represents the stress in any bar in fig. 3. Double lines represent compression, and single lines tension.

The correctness of this diagram has now to be proved. Beginning, as before, at the support A we easily see that 4 5 and 0 5 are the two forces. Knowing these, we determine the next ones, which meet at the points F and J. Here we stop; for if we proceed to the point G the *three* forces 7 8, 8 9 and 9 2, are unknown; and if we try to take the point D first, then again three forces have to be determined, namely, 7 8, 8 11 and 11 0. The diagram is, indeed, found by a somewhat differing method; but it being once given it is easy to be seen that it must be correct, for it gives stresses which are in equilibrium at each connecting point. The forces, for instance, acting upon the point G are given by the figures placed round G, namely, by 3 6 7 8 9 2 3. These figures, in fig. 4, are the angular points of a polygon of forces, and, as this is closed, we have equilibrium at G. Similarly for all other points. By following such a polygon round in the direction determined by any of its forces, we further ascertain which bars undergo compression and which have tension. In the polygon for the point G, for instance, the load G or 2 3 acts in fig. 4 in the known direction from 2 to 3. Hence, following round in the direction 2 3 6 7, &c., we see 3 6 acts from 3 to 6, and parallel in the elevation, or towards the point G. Thus 3 6 undergoes compression, aud so on for the others.

These diagrams show very strikingly how the stresses alter with the inclinations of the top and bottom beams. Suppose, for instance, we make the top beam in fig. 1 more inclined, then the line 4 5 in the diagram of forces will turn round the point towards the line 4 0. The point 5 then moves towards 0 in 0 5, whereby the lines 4 5 and 5 0 are rapidly shortened; and similarly with all the other lines in the diagram. Hence all the forces decrease by giving the top beam a greater incline, or by increasing the depths of the rafter.

The above is from the "Building News." The same subject is treated by James H. Cotterill, M. A., in "Engineering," under the following title:

On the Graphic Construction of Bending Moments.—It has long been known that the ordinates of a funicular polygon, corresponding to a system of parallel forces in one plane, represent the bending moments produced on a beam by the action of those forces; at least, such a principle has been employed in special problems, though, perhaps, never distinctly laid down as a general property of the funicular polygon. For instance, it must have struck every one who has considered this subject that the curve representing the bending moment at any point of an uniformly loaded beam is identical with the curve in which a chain hangs under a load, which, like that of a suspension bridge platform, is uniformly distributed horizontally. Also, it is not difficult to perceive that the multiplier by which the numerical value of the bending moment is obtained is the horizontal tension of the supposed suspension chain.

The remarkable construction now to be explained is founded on this property of the funicular polygon, and, as it appears to be very little known, I have thought that a short notice might interest the readers of this journal. It is, so far as I know, due to Prof. Culman, of Zurich; and I am acquainted with but one other writer who uses it, namely, Prof. Reuleaux, in his valuable work "Der Constructeur" (Note 1).

In Culman's work (Note 2) the properties of the funicular polygon are very thoroughly investigated, and a whole system of applied mechanics founded thereon; but the construction for bending moments, which appear to me to be of considerable value, may shortly be demonstrated thus: "Take, for

FIG. 3.

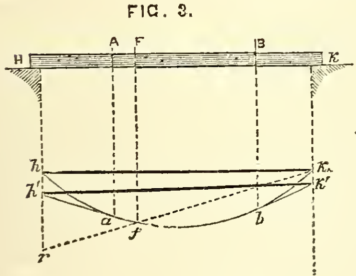

FIG. 1.

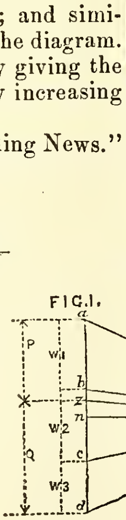

FIG. 2.

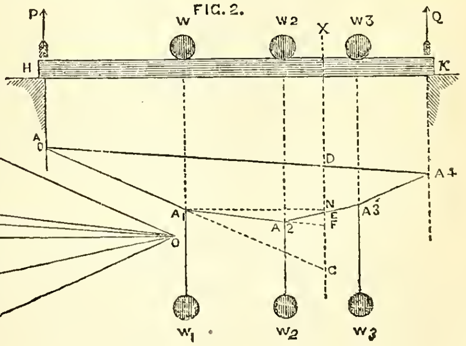

example, a beam, H K, supported at H K, and loaded with weights, W_1, W_2, W_3; it is required to find the supporting forces, P Q, and the bending moment at any section, X (Fig. 2).

Set off on a vertical line, ab_1 bc_1 cd, to represent the weights, W_1 W_2 W_3, respectively on any convenient scale (henceforward called the scale of tons.) (Fig. 1.)

Join a, b, c, d, to any convenient pole, O, thus forming a figure which may be called the diagram of forces, and draw the polygon, $A_0 A_1 A_2 A_3 A_4$, with sides parallel to Oa Ob Oc Od, and corners vertically below the supporting forces, P Q, and the load, W_1 W_2 W_3; then A_0 A_1 A_2 A_3 A_3 is the form in which a rope would hang if fixed at A_0 A_4, and loaded with W_1 W_2 W_3, for the sides of the triangles, $O\,a\,b$ $O\,b\,c$ $O\,c\,d$, are parallel to the forces which act at the points A_1 A_2 A_3, respectively. Suppose now A_0 A_4 to be joined, and instead of A_0 A_4 being fixed points, let the side, A_0 A_4, be a solid bar, and the closed funicular polygon thus formed be suspended by strings from the points of support of the beam. Then evidently the tensions of these strings are P Q; thus P Q are immediately got by drawing $O\,z$ parallel to the closing side, A_0 A_4, in the diagram of forces; for, from the equilibrium of the points, A_0 A_4, represented by the triangles, $O\,a\,z$ $O\,d\,z$; $z\,a$ represents P, and $z\,d$ represents Q.

Again, to find the bending moment at any section, X, of the beam, drawing the vertical through X, cutting the sides of the polygon on the sides produced, in D E F G; also draw A_1 N horizontal to meet this vertical in N, and in the diagram of forces, O n, perpendicular to $a\ b\ c\ d$.

Then by similar triangles

$$\frac{F\,G}{A_1\,F}=\frac{a\,b}{O\,b} \text{ and } \frac{A_1\,F}{A_1\,N}=\frac{O\,b}{O\,n}$$

$$\therefore \frac{F\,G}{A_1\,N}=\frac{a\,b}{O\,n}=\frac{W_1}{H}.$$

Where H is the horizontal tension in the funicular polygon represented in the diagram of forces by the polar distance, O n.

$\therefore$ H. F G$=W_1$ .A_1 N$=$moment of W_1 about X.

So in like manner

H. F E$=$moment of W_2 about X,
and H. G D$=$ " P " "
therefore H. D E$=$bending moment at X.

Thus the bending moment at any point, X, of the beam is the force represented by the polar distance O n, in the diagram of forces acting at an arm equal to the length of the intercept, D E, between two sides of the polygon. The rule, therefore, is, measure the polar distance on the scale of tens, and the intercept on the scale of feet; then the product is the bending moment in foot tons.

This result may also be obtained by considering A_0 A_1 A_2 A_3 A_4 as a girder, and applying the method of sections.

The construction here proved for three weights can evidently be extended to any number; its advantage consists mainly in the fact that the position of the pole, O, in the diagram of forces is entirely arbitrary, and can, therefore, be assumed so as to satisfy any convenient conditions. Suppose we require the stress on each bar of a half lattice girder loaded in any way, it will be convenient to choose a polar distance numerically equal to the depth of the girder, for then the intercepts corresponding to any point read off on the scale of feet will be the stress on the opposite bars in tons.

Or again we make the polar distance 10, then the intercept corresponding to any point read off on a decimal scale, with the decimal point moved one place to the right, is the numerical value of the bending moment. Thus a series of bending moments are obtained much more quickly than by any calculation method.

The construction will also be found of considerable value in estimating the effect of a partial load on a girder; an example will show what is meant. Let the beam H K be uniformly loaded between A and B; then to find the bending moment at any point we have only to draw the parabola h a b k, which would represent it if the beam were completely loaded, and at points in the parabola corresponding to a b, draw tangents cutting the verticals through H K in h' k'; then h' k', b a is the polygon for the partial load, the multiplier being the same as for the complete load. (Fig 3.)

The form which the construction assumes, when one or more of the weights is outside the points of support, is interesting. In this case the closing side of the polygon usually intersects two or more of the remaining sides; the corresponding points in the beam are points of contrary flexure, and converse f, if their position is known the polygon of moments is at once determined. For example, let H K be fixed at H, supported at K, and uniformly loaded; assuming the point of contrary flexure, F, we find the corresponding point, f, in the parabola, then $k\,f\,r$ is the closing line, and $h\,f\,b\,k\,f\,r$ is the polygon of moments.

It may be added in conclusion that the shearing force at any point of a beam is known at once from the diagram of forces, thus in the case of the beam first considered, the shearing force is $z\,a$ between P and W_1, $z\,b$ between W_1 and W_2, $z\,c$ between W_2 and W_3, $z\,d$ between W_3 and Q; this enables the stress on the diagonals of a half lattice girder to be obtained from the diagram of forces by drawing parallels to meet a horizontal through z.

Royal School of Naval Architecture, December, 1868.

RAILWAY STATION ARCHITECTURE.

THE LONDON STATIONS—REQUIREMENTS—THE ST. PANCRAS STATION.

The requirements of station architecture are discussed at length by the "Building News," from which we compile the following facts and conclusions. The light and elegant Moorish style is considered peculiarly adapted to iron construction, and hence to station architecture. The classical orders are exclusively for stone. Even the slender Corinthian or Ionic shaft, in iron, is manifestly a sham, and our common sense rebels against it. How, then, is it with the stout Doric column with its massive capital?

The Great Western station at Paddington is cited as at once elegant and suitable. It is in three spans, crossed by two transepts, an arrangement which gives it intricacy and picturesqueness, and conveys an idea of something approaching to comfort, if such a thing can possibly exist in connection with a railway terminus. The girders are pierced in the web with various devices; the columns are light and of Moorish character, and the whole is airy and elegant. The supports to the roof are in the way of nobody, the ventilation is perfect, and the roof is so low that it does not obtrude itself upon the neighborhood; if it did it would not be an offensive object. While Paddington terminus exists let no one say that any other must be either huge or hideous.

The Charing Cross (single span) is one of the monstrosities which it seems to be nobody's business to interfere with while in progress, and everybody's duty to condemn when completed. It is very long, very wide, very high, and very hideous. The walls afford capital accommodation for advertising boards, and this is the utmost that can be said in its praise. Were the walls lower and the roof a complete semicircle it would have been less offensive. It is, indeed, rivalled by the Cannon Street station, and it is difficult to award the palm of supreme ugliness to either without doing wrong to both. The large span is not justified by the plea of freedom from obstruction as to columns for support of two or more smaller spans, inasmuch as the platforms are both here and at Cannon street encumbered with lampposts, which are to all intents and purposes as much in the way as a column to support a girder. Neither is it justified on the score of superior ventilation.

The Southwestern station is in three spans similar to those at Paddington, and the lamps are suspended, not set upon standards. There is no pretension to elegance or ornament, but it accommodates its traffic, is well ventilated, and does not offend the eye.

Other stations in London are mentioned, and the cheapness and suitableness of several low spans, rather than one immense span is advocated. Columns are not objected to. They separate people into two lines and prevent jostling; they form spots where people can harbor and exchange a few words without being elbowed, and where a bag or parcel can be temporarily deposited with less risk than on the open platform.

The King's Cross station exhibits the failure of a too readily adopted constructive principle. For a long time the circular ribs, built up in the laminated method, and consisting of five two-inch planks bolted together, have been losing their shape; they have sunk at the crown of the arch, and are undergoing repairs. It is probable that they will have to be replaced with iron.

THE ST. PANCRAS STATION.—The construction of the new station of the Midland Railway is pronounced excellent. This immense work, recently completed, has been the subject of various essays and illustrations in the London press during the past year. The following graphic description is from the "Railway News." This building has the largest continuous roof of any building in the world. It is 690 feet long, and 240 feet wide. Bare figures, however, fail to convey such an idea of the structure as may be afforded by comparison with others familiar to our readers. The Central Transept of the Crystal Palace is 120 feet wide, or exactly half the width, and 384 feet long, or rather more than half the length of the Midland station. The dome of St. Paul's is 100 feet in diameter; two and a half of these domes might be brought into the station if it were 250 instead of 240 feet wide. Charing Cross station is 168 feet, Cannon street 188 feet wide; the Midland is 240 feet in width, or nearly half as wide again as the roof of Charing Cross.

There is, too, this great feature in the Midland that distinguishes it from all other stations and buildings of its class. There is no network of girders nor of rods intersecting each other at every angle, creating a maze of intricate iron-work, and detracting from the general effect of the bold outline which would otherwise be presented. Enormous iron ribs, in shape something like the monster jaw-bones of whales, and 25 in number, start from the ground on each side, and meet in the centre at an elevation of more than 100 feet above the floor of the station. Iron plates, secured by millions of rivets, build up these ribs, until each of them weighs something like 50 tons, and if bent straight would be 400 feet in length, or nearly the height of St. Paul's Cross from the ground! To prevent the feet of these ribs from starting outward there are fifty huge girders resting upon 1,100 iron columns, more than a foot in diameter, and which, like the string of the bow, keep the frame-work rigid and immovable. To make these binders still more secure, there are 2,000 other iron girders, which cross and recross, and form a network of iron bracing. All this is below the floor of the station, and it supports the roof of four and a half acres of cellars underneath the station.

This large area under the station is to be used for the storage of beer and merchandise, and contains fifteen ranges of cast-iron columns. There are forty-six columns in each range, or six hundred and ninety in all. They stand at about fourteen feet six inches apart. These columns, and the piers upon which the principals rest, have all their foundations upon the London clay. Over the clay is spread a floor of concrete seven feet thick, and upon that a broad sill-plate, upon which the columns are set. The spaces between the intersections of the girders are covered with Mallet's buckle-plates, and a surface is thus provided strong enough to bear, without deflection or rupture, any weight that may be brought upon it. In addition to the binding by the girders, the feet of the principals are further secured by a pair of bolts 24 feet long and four inches in diameter, which pass down through the piers, and are fastened to the anchor-plate below by nuts six inches deep These invisible bindings of enormous strength, are important contributories to the lightness and elegance of the great arch. Along the sides of the station, and outwards to the streets, ranges of arched spaces are built, to be let as shops and places of business. Their fronts, in the Gothic order, and which reach to about the height of the station platform, add greatly to the effectiveness of the immense structure by their quiet enrichments, and by dividing the vast surface of dead wall that would otherwise have been presented.

The walls of the station, unlike those of Charing Cross and Cannon street stations, perform no part in sustaining the roof of the building; this work being thrown, as we have explained, entirely upon the iron ribs which spring from the ground floor. The walls are picked out with white stone; a tesselated frieze of handsome design, inlaid with colored tiles, forms an agreeable ornament, the moulding above which is surmounted by an iron cresting of floral design, the leaves curling inwards from the cornice. Recessed pointed arches and small quatrefoil windows at intervals in the side walls complete the architectural effect as viewed from the interior, which presents a light and agreeable appearance.

The construction of this gigantic roof necessarily involved great difficulties. An enormous traveling stage; similar to that used for the domes of the Exhibition building of 1862, was built up. This stage is 100 feet in length, width 240 feet, depth 90 feet; it contains more than eight miles in length of solid timber, and weighs over 1,300 tons. The huge mass rests upon small wheels, and may be moved about on its tramway as desired, by levers. Such is the extent of the work that there were employed upon the station for the greater part of the time 6,000 men, 1,000 horses, and 100 steam lifts of various kinds.

In the designing, as in the carrying out of this noble station and approaches, Mr. W. H. Barlow has completed a work which will deservedly place his name among those of the most eminent of his profession. The external architecture is the design of Mr. Gilbert Scott. The detail drawings of the iron work were furnished by Mr. Ordish, and the work was supplied by the Butterly Iron Company.

Gigantic Water Works.—A manufacturer of Lyons proposes to supply that town with an amount of water which no city in the world possesses. His plan is to draw from the Lake of Geneva ten tons of water per second, or 864,000 tons in twenty-four hours. The population of Lyons being 330,000 souls, this would give each 2,618 litres of water per diem. Rome, the best supplied city in the world, has 1,500 litres per head per diem, New York 568, Marseilles 470, Bordeaux and Paris each 170, London 110, Brussels 80, Geneva 74, and Lyons, at present, only 60 litres. The proposed canal or conduit would be divided into three sections: (1) An open canal 55 miles long, having a water section 21ft. wide, and about four ft. deep; (2) a covered conduit in masonry, 31 miles long; and (3) nearly eight miles of syphons for the crossings of the valleys.—*The Engineer*.

Good Marine Engineering.—The British iron-clad Hercules, 325 feet long, 59 feet wide, and of 8,600 tons displacement, recently steamed 14.7 knots, or over 17 miles per hour, while drawing 23 feet forward and 26½ feet aft, and developing 8,528 horse power. The remarkable feature is that the engines complete and boilers with water weigh but 1,095 tons, or 2½ hundred weight, per horse power.

MORTON'S EJECTOR-CONDENSER.

Compiled from Prof. Rankine's paper before the Institution of Engineers in Scotland, and the subsequent discussion, and from articles in "Engineering."

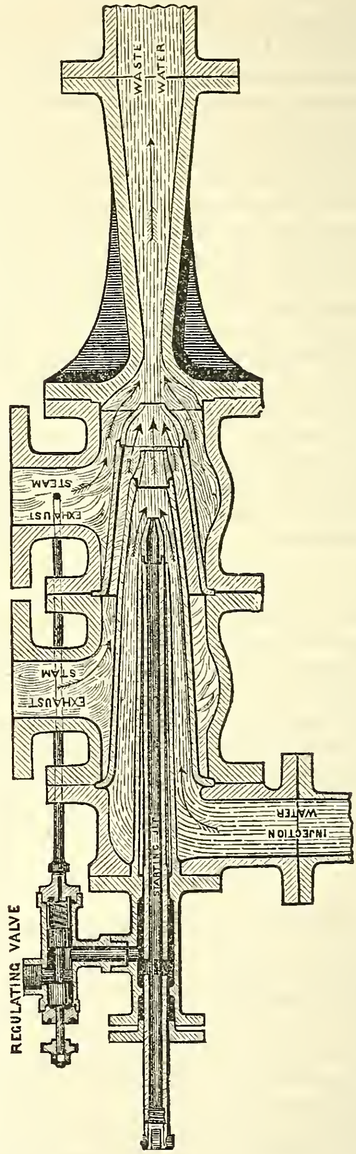
One of the most remarkable devices connected with the steam engine, that has appeared since the Giffard injector, is the condensing apparatus described in this article. Indeed, Professor Rankine pronounces it the most important improvement made in the steam engine, since the days of Watt. Its action is briefly this: While in the ordinary condenser, the force of the steam and water rushing in are entirely wasted, and require a pressure of 0.6 lb. per square inch on the steam piston to pump them out and maintain a vacuum, the Morton condenser utilizes the force of the steam and water entering it, and dispenses with the air pump. The exhaust steam and the condensing water simply rush into a sort of Giffard injector, and instantly come out of it in the form of hot water (and the contained air) without other assistance.

The experiments described were made at the request of Messrs. Neilson Brothers. The ejector-condenser, invented by Mr. Alexander Morton, was applied to a pair of vertical inverted direct-acting steam engines, which exerted collectively a power averaging about 24 indicated horse power. The nominal power of these engines is collectively seven horse power, if we apply the ordinary rule for low pressure engines, or fifteen horse power if we apply the ordinary rule for high pressure engines. The dimensions of the engines and of the condensing apparatus, and the results of the experiments, are given in detail in the annexed table; but as regards the engines it may be convenient to state here that their two cylinders were of eighteen-inch stroke, and about ten and a quarter inch diameter, that they ran at from 93 to 140 revolutions per minute, and that the steam pressure gauge indicated from 30 pounds to 40 pounds on the square inch above the atmospheric pressure, which at the time was 14.75 pounds on the square inch. It may be remarked that the experiments throw light on other questions besides the efficiency of the new condenser; and in particular, that the accurate measurement of of the quantity of condensation water, and of its change of temperature, affords the means of calculating the total expenditure of steam, and comparing it with the quantity of steam effectively used in doing work, as indicated by the diagrams. The circumstances under which the experiments were made were, to a certain extent unfavorable to the apparatus, for the pipe which supplied the tank from which the cold water was drawn for condensing the steam was of too small diameter, and the engines had from time to time to be stopped in order that the tank might be refilled.

Principle of Action.—The principle of the invention may be described as follows: In every injection condenser the cold water rushes into the vacuum with a velocity of 43 feet or 44 feet per second or thereabouts. The exhaust steam rushes from the cylinders into the condenser with a velocity which is many times greater than that of the water. In the common condenser these rapid motions of the water and of the steam are completely checked, and their energy is wasted in agitating the fluids in the condenser, and ultimately in producing heat, and hence it becomes necessary to use an air pump in order to extract the water, air and uncondensed steam from the condenser. The power expended in working a well-proportioned and well-constructed air pump is known by experiment to be equivalent to that which would overcome a back pressure on the steam piston of from half a pound to three-quarters of a pound on each square inch of its area, or, on an average, about 0.6 of a pound on the square inch, and that amount of power is lost through the wasting of the energy with which the jets of water and steam rush into the condenser. In the ejector-condenser the motion of those jets meets with no interruption, and its energy is found to be sufficient, without any assistance from pumps, to carry all the water, air, and uncondensed steam (if any) completely out of the condenser and into the hot well, and thus to save the power which would be required to drive an air pump.

Paradoxical as Giffard's injector appeared, at first sight, its action admitted of perfectly clear explanation. In a boiler under pressure of 100 pounds per square inch, equal to a head of water of 230 feet, the water would rush out of any opening with a velocity (were there no friction, atmospheric resistance, or loss of head) of about 121 feet per second. But were an opposing jet to move with agreater velocity, it would drive back the escaping steam and force its own way into the boiler. This is what happens in the injector, and for a simple reason. A jet of steam moving with a velocity of perhaps 1700 feet per second is instantly condensed in perhaps twelve times its own weight of water. The combined jet will then move with one-thirteenth its former velocity, or about 131 feet per second, the motion of the steam being wholly imparted to the water. Thus the jet, properly directed, enters the boiler. In Morton's condenser, the escaping exhaust steam, properly directed, is condensed in, and its own motion imparted to, a jet of water previously set in motion by a small steam jet, and the experiments appear to show conclusively that the lateral action of the jet is sufficient to draw with it all the air that collects down to a vacuum of twelve pounds or thirteen pounds.

Mr. Morton's explanation of the action is that a jet of water in rushing into the vacuum has nearly sufficient power to take itself out, and the impulse of the exhaust steam from the cylinders makes up the energy that the jet looses in friction.



Description of Apparatus.—The principal parts of the condensing apparatus on which the experiments were made may be summarily described as follows: The cold water passes from the tank to a conoidal nozzle; the area of the orifice of that nozzle is about equal to that of the injection sluice of a common condenser suited for the same engine; that is to say, about $\frac{1}{250}$ part of the collective area of pistons. Enveloping the cold water nozzles are a second and a third nozzle of nearly similar figure; these bring the exhaust steam from the two cylinders respectively. The middle nozzle has an orifice a little larger than that of the innermost, or cold water nozzle; the outermost nozzle ends in a throat or contracted vein, a little larger still, beyond which is a gradually widening trumpet-shaped mouthpiece, leading to a pipe which ends at the hot well. The condensation of the steam takes place in the interval between the orifice of the cold water nozzle and the throat of the outermost nozzle.

When this condenser was first constructed there was no stop-cock for shutting off the injection water, and in starting the condenser it sometimes happened that the attendant would shut off the main steam valve while there was a vacuum in the cylinders, and thus the water was liable to get into them. The inventor has now—that is since Professor Rankine's experiments were made upon the condenser—added a regulating spindle and cylinder, which cylinder contains a piston valve that opens with a spring immediately that the perfection of the vacuum in the condenser is interfered with. By means of this central regulating spindle the injection water current may be most nicely adjusted, or it may even be cut off instantaneously, and the engines can thus be made to work as high pressure engines at pleasure; indeed, its action is so certain and instantaneous that a cylinder full of air may be completely expelled during one revolution of the engine. When the engines are at work, and the regulating valve in action, the latter shuts off the central steam jet; and should any person open a grease cock, or otherwise admit air into either of the cylinders or the condenser, the loss in vacuum is instantly communicated to the regulating valve by the pipe. The action allows the valve to open the steam jet, and thus to displace the air.

While engaged in perfecting this new invention, Mr. Morton experienced the greatest amount of difficulty in connection with the exact parabolic shape which the discharge pipe should assume. This appendage may be regarded as the most important part of the apparatus, for without it the action of the apparatus would be practically useless for a condensing engine, as the steam on leaving the cylinders would require to be much above atmospheric pressure before any water could possibly be discharged. By gradually imparting to the discharge pipe the trumpet-mouth form, shown in the engraving, it was found possible to produce a vacuum of 13 lb. per square inch, with a water pressure on the entering side of the condenser of only two lb.; while to produce a similar vacuum required a water pressure of 50 lb. per square inch if a *vena contracta* nozzle were substituted for the trumpet-mouth of the discharge pipe; or, in other words, a water pressure of 50 lb. could be reduced to two lb. by gradually widening the mouthpiece to its present form, while the vacuum remained the same, and this without the use of any steam in the experiments. Prof. Rankine regards Mr. Morton's application of the trumpet-shaped mouthpiece to the steam engine as being quite a new and original invention, and indeed, as probably the most important improvement in the steam engine since the time of James Watt; and Sir Wm. Thomson considers the production of a vacuum of 13 lb. by the use of this appliance as a most wonderful result in a dynamical point of view.

The Experiments.—Table of experiments made on the 27th October, 1868, on a pair of engines at the works of Messrs. Neilson Brothers:

Cylinders:	
Area of each, allowing for piston rods, about	80 square feet.
Stroke	1.5 foot.
Cold Water Nozzle:	
Diameter 13-16	=0.8125 in.
Area	0.638 sq. in. =0.00443 sq. ft.
Water Tank:	
Area 8 ft. × 3½ ft.	=28 square feet.
Mean depth of surface below level of nozzle	5.25 feet.
Waste Water Nozzle:	
Diameter of throat 15-16 in.	=0.9375 in.
Area of throat	0.690 sq. in. =0.00479 sq. ft.
Diameter of mouth-piece	3.0 in.
Area of mouth-piece	7·07 sq. in. =0.0491 sq. ft.
Cold Water Supply:	
Mean rate of flow in cubic ft. per min., 28 ft.×0.41=11.48	=716.4 lb.
Do. per second, 0.1913	= 11.94 lb.
Velocity of cold water through nozzle, ft. per second, $\frac{0.1913}{0.00443}$	= 43.2 lb. per sq. in.

Head due to that velocity......	29 ft.= 12.57
Add mean height to which water is lifted............	5.25 = 2.275
Total head	34.25 =14.845

Temperature................. 47° Fahren.

Mean work per minute done in raising and propelling water jet, exclusive of friction, 716.4×34.25............. =24537 ft. lb. =0.744 I. H. P.

Barometer: 30.05 in. mercury=14.75 lb. on the square inch.

Abstract of Principal Mean Results.

Mean power saved by dispensing with air pump, indicated horse power	1.0
Mean indicated horse power of engines	23.8
Mean back pressure in cylinders, lb. on sq. in.	4.05
Mean vacuum in cylinders, lb. on the sq. in.	10.7
Mean vacuum shown by gauges, lb. on sq. in.	12.0
Mean vacuum shown by gauges in inches of mercury	24.5

About two-thirds of the indicated power were due to the vacuum in the cylinders.

	deg. F.
Temperature of the cold water	47
Mean temperature of waste water	$83\frac{1}{2}$
Mean increase of temperature	$36\frac{1}{2}$

The completeness and efficiency of the condensation were tested by vacuum gauges, and by indicator diagrams. By both means of testing, the left-hand cylinder, which exhausted into the middle nozzle, showed a rather better vacuum than the right-hand cylinder, which exhausted into the outermost nozzle. The average results of the whole of the experiments were as follows:

Mean vacuum shown by gauges, in inches of mercury	24.5
Mean vacuum shown by gauges, in lb. on the square inch	12.0
Mean vacuum in cylinders, during return stroke, as shown by the indicator diagrams; lb. on the square inch.	10.7
Which, being subtracted from the atmospheric pressure at the time	13.75
Leaves, as the mean back-pressure in the cylinders during the return stroke, in lb. on the square inch	4.05

The back pressure in different experiments ranged between 3 lb. and $4\frac{1}{2}$ lb. on the square inch. These results are at least as good as the average results as to vacuum and back pressure obtained by means of the common condenser; and they show the condensation of the steam and expulsion of the water, air and vapor, to be at least as complete and efficient.

It is estimated that the saving of power through the dispensing with an air pump is equivalent to the doing away with a resistance of 0.6 lb. per square inch area of steam pistons, and it is found to be, on an average of the several experiments, just one horse power, being about 4 per cent of the mean indicated power of the engines. The energy of the jet of cold water is about $\frac{3}{4}$ horse power. This forms the greater part of the energy which is wasted in the common condenser, rendering an air pump necessary.

The temperature of the cold water employed was 47° Fahr., and the temperature of the discharge water was $83\frac{1}{2}$° In common condensing engines the temperature of the discharge water would generally be about 120° with a similar vacuum, a fact which indicates that the new condenser consumer a larger amount of water than is consumed by the ordinary condensing jet. This is admitted, but it must be remembered that the latter gives a much hotter discharge water than the former. There is this fact, also, that the vacuum has recently been improved 1 lb. per square inch by making comparatively trifling alterations in the apparatus. The condensing water has been experimentally reduced $2\frac{1}{2}$ times since the experiment described, with a proportional increase in the temperature of the discharge water and a loss in vacuum of 1.5 lb. The quantity of water now used is stated to be the same as with the ordinary condenser.

As to the height to which the discharge water could be lifted, Mr. Morton states that if the steam leaves the cylinder at about the atmospheric pressure, the water could be forced about 15 ft. high ; a pressure of 5 lb. would force it 20 ft. high.

The abstraction of the air is perhaps the only thing that is really puzzling in he matter, unless it be that the very rapidity with which the steam concentrates upon and within the passing jet of water carries the air wholly against or even into the jet also.

But there is one thing in the record of experiments which requires some explanation. The units of heat imparted to the injection water were from 2.1 to 2.9 times those contained in the heat of condensation of the steam shown by the indicator. Not only this, but the steam represented by the increase of temperature imparted to the injection water amounted to more than 60 lb. per indicated horse power per hour. The different indicated horse powers recorded, the pounds of steam condensed per minute, and the pounds of water consequently used, as steam, per horse power per hour, were as follows, the last column being calculated in "Engineering" from the two first:

I. H. P.	Steam used per Minute. lb.	Water per I. H. P. per Hour. lb.
28	26.0	55.7
20	22.0	66.0
26	27.0	62.3
25	26.1	09.8

The quantity of steam used, representing from 7 lb. to 8 lb. of coal per indicated horse power per hour, appears excessive when the good rate of expansion, good vacuum, and good rate of piston speed are considered. It might be suspected that, notwithstanding the assertion that no steam was used direct from the boiler to keep the jet in motion, the little regulating valve shown in our illustration was open, and thus it might prove that as much live steam was used to work the condenser as to work the engines themselves. This, however, is not said as in any way conclusive, but as a matter requiring explanation.

Cost, Economy and Advantages.—As to cost of construction, Mr. Morton stated that his condenser would not cost more than one-fourth as much as the ordinary condenser and air pump.

The conclusions from the experiments are: First, that the action of the ejector-condenser is at least as efficient as that of the common condenser, with its air pump; and, secondly, that by the use of the ejector-condenser the power required to drive the air pump is saved. The construction is very simple, it has no moving parts which can get out of gear. It can work at any speed of engine, while a high speed of air pump is attended with difficulty; and it overcomes the objection which often arises from placing the air pump horizontally. When the engines are stopped, the vacuum may be maintained for any period of time, by simply opening the central starting steam jet, so as to overcome the friction of the water through the nozzles. The advantage of having a continuous vacuum in maneuvering marine engines in port is of great importance to the marine engineer, especially so in war vessels. In order to maneuver them with facility, in action, this result has been sought in naval vessels by means of independent air pumps. Mr. Morton said that with a small head of water, steam could be wrought down to the finest pressures. H ehad had that engine working at 28in. or 29in. vacuum by adding a head of water of a few feet to that condenser.

Professor Rankine believes that when the apparatus gets fair play, it will give as good results as the surface condenser; at present the results are as good as those with the common injector condenser. While the ejector-condenser is applicable to all kinds of land engines, it seems to be even more especially valuable as an appliance on board river passenger steamers, in which reduction of weight to the lowest possible amount is of the very utmost importance. There is also this advantage in applying Morton's condenser to marine engines, that it may be placed at any height in the vessel, and not necessarily at the lowest level, as is the usual practice with the ordinary form of condenser. It has been suggested that the apparatus might be of still further service in steam vessels by ejecting the water in a direction opposite to that in which the vessel is sailing, and thus assist in its propulsion—acting as a sort of Ruthven's propeller.

The new condenser cannot, of course, give distilled water for the boilers, as is done by surface condensers. Mr. Morton has, it is true, proposed to cool his injection water, originally fresh, by circulating it through a refrigerator, but with water in the hot well, at a temperature of only 80°, or even 110°, or, still more, 120°, it would require a refrigerator many times larger and more costly than a surface condenser to cool it again, by means of sea water at from 50° to 70°, to say nothing of the pumps required for circulating the cooling water.*

That the ejector-condenser is really a very effectual condenser at a low first cost may be inferred from the fact that the Scotch engineers have, in numerous instances, shown an anxious desire, and even a determination to make practical use of the appliance. It has already for some time been in operation at the Lugar Ironworks, in connection with an engine that was made some twenty years ago. Messrs. Robert Napier and Sons, marine engineers and shipbuilders, Glasgow, have lately ordered a pair of engines, with Morton's condensers applied, to be erected at their works at Govan. We understand that Messrs. William Simons and Co., shipbuilders and engineers, Renfrew, are busily engaged in making a pair of twin screw engines on Morton's principle of condensation; and other marine engineering firms on the Clyde are framing their contracts in accordance with their intention to apply the ejector-condenser. Some experiments recently made by Mr. James R. Napier, F.R.S., with the injection water heated to a temperature of 80° Fahr., show that even in warm climates the new condenser will not vary much in vacuum, and that practically it will give a vacuum very nearly equal to that which is due to the temperature. The experiments referred to were so satisfactory that Mr. Napier has resolved, we understand, to apply the Morton condenser to the engines on the Godavery river steamers, built by Messrs. Randolph, Elder and Co., for the Indian Government.

* Lighthall's refrigerator requires no circulating pump.—*Ed. Van Nostrand's Magazine.*

EXAMINATION OF CIVIL ENGINEERS.

Compiled from the "Building News."

A resumé of the questions submitted to candidates for engineer appointments in India. cannot fail to be important to young engineers, and is of interest to general readers. The questions in the first division referred to cements, concrete, mortar, &c. The candidates were required to describe Portland cement, its characteristics, the raw materials from which it is made, and the proportions used. Also the methods of manufacture and the machine, and mode of testing adopted by the engineers of the Metropolitan Board of Works. The proportions of sand to use for mortar had to be stated, and the best qualities of sand for cement mortar named; dimensions and weight of the largest concrete blocks that have been used in harbor works, and a description of the means employed for placing them *in situ*, and where so employed.

The examiner strongly recommends a careful study of Mr. Henry Reid's book, lately published on this subject.* In his remarks on the writing of candidates he advises the cultivation by engineers of a clear, concise, and vigorous style of expression, and he directs their attention to the masterly reports and writings of Smeaton, now unfortunately out of print, but extracts from which, together with those of Watt, Telford, the elder Rennie, Stephenson, Brunel, Locke, and others, he hoped to see shortly published. Such a work, he thinks, would be to the engineer what the Despatches of Wellington are to the military man.

The questions of the second division relate to building materials—brick, stone, timber, &c. Statements were required of the candidates' opinions as to the selection of clay suitable for bricks, its preparation for the moulders, methods of moulding, and arrangements for burning, the latter to be accompanied by a free-hand sketch. Candidates were required to describe the different sizes and kinds of bricks, to illustrate the various bonds employed, and to explain how a bond is sometimes defective in a two-brick wall. A description had to be supplied of the various kinds of stone and timber, and the principal processes employed to preserve the latter from decay and iron from corrosion. The principles of the artesian well, Norton's tube pump, and Mather and Platt's apparatus for well-boring and coal sinking, were required, with particulars of existing wells sunk on the artesian principle. Concrete, now coming more largely into use for building operations, the importance of fuller acquaintance with that material and its capabilities, is insisted on.

The construction of bridges, especially suspension bridges, forms an important part of the examination. Candidates were to describe the difference between the ordinary suspension bridge and a bridge (of which illustrations were furnished) stiffened by suspension rods from the towers to various points in the floor. They had also to state approximately the area of iron required in one of the chains of a suspension bridge having two or more spans of ordinary construction, both at the points of support, viz.: top of tower and at the centre of span; the span being 500 feet, and the versed sine of the curve formed by the chains being 40 feet; the weight of one chain, together with its load, being half a ton per lineal foot, and the strain upon the iron not exceeding five tons per square inch of section. A description of the construction of the Menai, Lambeth, Clifton and Niagara Falls suspension bridges was required, and the spans of the largest bridges hitherto constructed, with the means adopted to obtain a rigid roadway. Free-hand sketches had to be made to accompany descriptions of Mitchell's screws for cast iron bearing piles for piers of bridges, foundation supports for lighthouses, jetties, &c.

The great importance of the study of architecture is strongly insisted upon. The drawing which accompanies the questions is an original design of a range of public offices with a large dome rising in the centre, and flanked by two smaller ones of similar external construction. Candidates were expected to furnish a description of the methods of its erection, to name the style, and to distinguish the different parts. Most of the questions on architecture are of a very elementary character.

The concluding list of questions bears on iron and its applications. The principal things required of the candidate were, statements of the limits in scantling embraced in the trade quotations for "bar iron"—say, in the cases of "flat," "round," and "square" iron; the difference in price of bar iron and angle iron; the limit in dimensions of angle iron comprehended in the said

* And largely compiled without credit from Gen. Gillmore's work on limes and cements.—*Ed. V. N.'s Magazine.*

difference in value, and the usual scale of additional charges for angle iron exceeding the limited dimensions; the price per ton of boiler iron, as exceeding that of bar iron, and the extra charges known in the trade as "best" and "best best;" also, the meanings of the terms "singles" and "doubles;" the comparative costs of steel and iron, with their respective advantages. The concluding question requires by way of answer a description of the process of manufacture of corrugated galvanized iron.

The list of books recommended by the examiner is as follows: "The Roorkee Treatise on Civil Engineering," edited by Major J. C. Medley, R. E.; "The Elements of Practical Hydraulics," by S. Downing, LL. D.; "Practical Treatise on the Manufacture of Portland Cement," by Henry Reid, C. E.; "Irrigation in Southern Europe," by Lieut. C. C. Scott Moncrieff, R. E.; "Italian Irrigation," by Colonel R. Baird Smith, R. E.; "On Public Works in India," by Sir Arthur Cotton, R. E.; "Account of the Ganges Canal," by Colonel Sir Proby Cautley, C. B.; "Ferguson's Works on Architecture."

GAS AS A CALORIFIC AGENT.

"Gas-Light Journal."

While the use of coal-gas for illuminating purposes has extended rapidly, in this country at least, its adoption as a calorific agent has been so slow as to disappoint the hopes of its early advocates. The advantages claimed for gas in this respect are cleanliness and freedom from trouble, it being unnecessary to carry coal or other fuel to feed the fire, or to remove ashes, etc. The rapidity with which heat may be generated and the ability to instantaneously extinguish the fire are great recommendations—particularly in summer when it is desirable to perform the duties of the *cuisine* with as little elevation of temperature as possible.

In England, and particularly in London, gas is largely used for cooking, and it is said to perform its office most acceptably. For families living in apartments, where the trouble and expense of carrying coal or other fuel would be great, gas has proved a great desideratum. By means of approved burners, and admixture with the proper portion of atmospheric air at the time of consumption, a large amount of heat is generated, and where sufficient ventilation may be had, the products of combustion are readily conveyed away, causing no inconvenience or injurious results. Possessing these advantages, it may appear strange that it is not more generally adopted; doubtless it would be, but for the high price of gas in this country; the ordinary methods for generating heat have the preference because of their economy. The probability is that if the price of gas were reduced, so as to make it practicable to employ it for heating, the demand for it would increase in a large ratio, and the concession might be more than atoned for in the enlarged sales which would undoubtedly follow.

That the calorific properties of gas are equal to other agents used for heating, is proved by the fact that in analytical chemical laboratories, charcoal and other fires have been, to a considerable extent, replaced by gas, and the operations of boiling, evaporation, fusion, ultimate organic analysis, and even cupellation, are now performed by easily regulated gas furnaces, their use conducing far more to the personal comfort of the operator, than the troublesome and cumbersome stoves formerly employed. The inventions of gas furnaces, such as are constructed by Griffin and others in England, and Krause and Haskins in this country, have displayed much ingenuity, and, by their use, the laboratory of the chemist presents a much cleaner appearance than formerly—no dangerous sparks or cinders being formed, nor ashes being blown about the room, to the detriment of other substances in the vicinity.

From the success attending the use of gas stoves in the laboratory, it is safe to assert that many of the operations of the household could be performed in the same manner.

The introduction of the improved process of manufacturing gas by the Gwynne-Harris plan of decomposing high steam to produce hydrogen as a heating agent, and for a motive power in lieu of steam power, is commencing a new epoch in the history of political and domestic economy. The same process applied to the ordinary coal gas manufacture lessens the first cost of production so greatly that it will soon be a matter of consideration with gas companies whether the selling price may not be lessened, with a view to its introduction into these new industries; thus opening a much more extensive demand, which, in the aggregate, will largely increase the dividends of gas companies, and add a new element to the progress of the age.

BRIDGE CONSTRUCTION.

Mr. S. S. Post, of New York, has designed an iron bridge for the Mississippi, at St. Louis, having 350 feet clear spans. This work was fully illustrated in "Engineering," July 24. The August 7th number of that journal gives the greater portion of the report of the "Committee on Superstructure and Approaches," at the Convention of Engineers, assembled at St. Louis, August, 1867. To this report figured diagrams for girders 368, 264 and 160 feet long were attached, solely to show the relative maxima of the strains to which the several parts of the girders are subject sometime during the passage of a given, irregularly distributed, moving load. To make the comparison a fair one, the girders were as nearly *similar* in their arrangement, and as uniformly divisible into panels as practicable. Assuming their bearing points to be two feet from the ends, the actual spans were 364, 260 and 156 feet, each of which is a multiple of thirteen feet. The figured diagrams happened to be arranged in consonance with Mr. Post's notions of economy in the use of materials, as exhibited in the design above mentioned. The bays or panels of the horizontal members of the girders were thirteen feet long, except that the chords had a half bay of six and a half feet at each end. The end posts were vertical, but the intermediate ones—the strut braces—were inclined *half a bay.* The heights of the respective girders were three and a half, two and a half, and one and a half bays, making the inclination of their struts one-seventh, one-fifth, and one-third of the height. The tie braces, except the end ones, were inclined 45°, and counter ties were introduced in each panel to the ends of the girder.

To this arrangement a writer in "Engineering" makes two principal objections. 1st. He thinks the counter braces are unnecessary, except "for a short length of the girder at its center"; and, 2d, on account of the particular inclination of the braces. On this latter point he says: "Another feature in the design challenges criticism. The diagonal ties are placed at an angle of 45°, and the struts at an inclination of one horizontal to seven vertical. Now, as we have already said, the useful work done by a strut or tie is the transference of the load towards the piers. It follows, from this, that a *vertical* strut is theoretically of no value at all; it is merely so much additional load on the girder. The load is just as far off its ultimate destination—the pier—when it is transmitted by the vertical strut to the bottom of the girder, as it was when at the top. An infinite number of vertical struts and ties, and, consequently, an infinite weight of metal so disposed, would not transmit the load to the piers. With the struts arranged as in the St. Louis bridge, the load is nearer the pier when transmitted through the strut, to the extent of one-seventh of the depth of truss, and with the ties at an angle of 45°, it is transferred by them a further distance equal to the depth. The question is, whether this total amount of one and one-seventh the depth, the distance which the load is passed on by each triangulation towards its ultimate destination, is as large as it should be. This problem is easily solved. From what has been already advanced, it will be seen that the most economical inclination of tie and strut will be that in which the cost of these members in one triangulation, divided by the horizontal length of same, is the minimum. The proper inclination of the tie and strut will be mutually dependent; with a different construction of strut the angle of the tie would also differ. If struts and ties were the same cost per foot to sustain the same strain, the proper angle would be 45° for both. As the strut is, however, always more costly than the tie, it follows that the economic angle for the tie will be more acute, and for the strut more obtuse than that angle. To determine the most economic angle for the truss we are criticising, we must approximate to the comparative costs of the wrought iron ties and cast iron struts. Assuming the average strain on the latter as one-fourth the amount on the ties per unit of area, and taking the cost per ton of cast iron as one-half that of wrought, we obtain the proportional cost of the strut, for each ton per square inch strain $\times$ one foot long, as double that of a tie under the same conditions. This is a very liberal allowance for the strut; in fact, on De Bergue's system they might be constructed in wrought iron for a considerably less amount."

"Now, if $x =$ the horizontal distance between the two ends of the tie, and $y =$ the same distance in the strut, the useful work done by each triangulation will be the transference of the load the distance $x + y$. Again, the cost of the tie will be proportional to its weight, that is, to the strain upon it multiplied by its length. But the strain also is proportional to the length; hence the cost will be proportional to the square of the length, or in terms of the depth to $1 + x^2$. In the same manner the cost of the strut will be proportional to $2 + 2y^2$. The true measure of the economic value—the cost per foot—will, consequently, be proportional to $\frac{3 + x^2 + 2y^2}{x + y}$. It is only necessary, therefore, to determine the values of x and y when the preceding expression is the minimum. It will be found that $x = \sqrt{2}$, and $y = \sqrt{\frac{1}{2}}$; hence, the inclination of the tie, instead of being 1 to 1, as designed, should have been 1.4 to 1, and of the strut 0.7 to 1, instead of $\frac{1}{7}$ to 1. With the most economic inclination the cost of the web would be proportional to 2.86. With those adopted we obtain by substituting $x = 1$, and $y = \frac{1}{7}$ in the preceding equation, the cost of web proportional to 3.52, exhibiting an excess of some 23 per cent. With vertical struts the cost would be proportional to 4; hence the inclination of the struts, small though it is, effects a saving of 12 per cent. With the struts and ties all at angles of 45°, the cost would be proportional to 3, and the same result would be attained by arranging the ties at an inclination of $1\frac{1}{2}$ to 1, and the struts at $\frac{1}{2}$ to 1, so that considerable latitude is allowed for practical contingencies."

We give, below, the reply* of Mr. Post to the objections raised, and, we think, considering the ability of the parties to the discussion, that it will form an interesting as well as a useful chapter in bridge construction. Mr. Post believes the criticism to be in some respects just, but in other respects he regards the subject under a very different aspect from that assumed by the English writer. He says:

The doctrine that the transference of the weight of the structure and its variable load to the abutments can be accomplished only by means of inclined members, is fully admitted and needs no argument. It is also admitted that both the struts and the ties, connecting the upper and lower flanges, should be inclined. The Reviewer and myself differ somewhat as to the angle of inclination that ought to be given to the ties and to the struts. He will, undoubtedly, concede that acting *alone*, or in pairs, independent of any strut, the tie-brace will produce the greatest useful result when its inclination is 1 to 1, or 45° with a vertical.

Economy in the use of material in a brace requires that the quantity or volume should be the least in proportion to the distance spanned; that is, the greatest economy is when the volume divided by the horizontal reach gives the least quotient; or is a *minimum*. So long as the tie or strut remains vertical the quotient is infinitely great. It is then only an auxiliary, not a direct agent in the transference of the weight toward the abutment.

The strength of the tie depends upon its section, without regard to the length, neglecting its own weight. The section of the tie is always as the weight or stress in the direction of its length. The volume of the tie, when vertical, is proportionate to the product of the length into the weight suspended. When the tie becomes inclined, its length increases as the secant of the angle of inclination, and the stress also increases as this secant. When the maximum useful inclination is reached, this secant becomes $\sqrt{2}$ and the volume of the tie $l\sqrt{2} + W\sqrt{2} = 2\,l\,W$. That is, in passing from the vertical state to an inclination of 45°, the tie doubles its volume.

In the case of a strut, its volume conforms to a very different law in regard to its length and sectional area. Hodgkinson's formula for the strength of a cast iron cylindrical pillar, with rounded ends, and not less than 15 diameters in length, is

$$W = 33379 \times \frac{d^{3.76}}{l^{1.7}} \qquad (1)$$

in which $W =$ the breaking weight in pounds, $d =$ the diameter in inches, and $l =$ the length in feet.

Let $V =$ the volume in cubic inches of a pillar, the section of which is a circle; then

$$V = \frac{\pi}{4} d^2 \times 12\,l = 3\,\pi\,l\,d^2 \qquad (2)$$

From equation (1),

$$d^{3.76} = \frac{W\,l^{1.7}}{33379};\ d = \left(\frac{W\,l^{1.7}}{33379}\right)^{\frac{1}{3.76}};\ d^2 = \left(\frac{W\,l^{1.7}}{33376}\right)^{\frac{1}{1\ 88}} \qquad (3)$$

Substituting this value of d^2 in equation (2).

$$V = 3\,\pi\,l\left(\frac{W\,l^{1.7}}{33376}\right) = 3\,\pi\left(\frac{1}{33376}\right)^{\frac{1}{1.88}} \times W^{\frac{1}{1.88}} \times l^{\frac{3.58}{1.88}}. \qquad (4)$$

* "Engineering," Jan. 8, 1868.

$$V = 0.036998 \times W^{\frac{1}{1.88}} \times l^{\frac{3.58}{1.88}}. \qquad (5)$$

From this it appears that the volume of a cast iron strut increases as the 0.35+ power of the weight imposed, and the 1.9+ power of the length.

Now, assuming the vertical height or altitude to remain constant, when the strut becomes inclined, its length increases and its stress also increases, both as the secant of the angle of inclination and its volume is greatly increased.

Putting V_1 for the new volume, m for the exponent $\frac{1}{1.88}$, n for $\frac{3.58}{1.88}$; $A=$ the coefficient 0.036998, $W=$ the weight, and $l=$ the altitude, as before, and make $x=$ the tangent of the angle of inclination, then $lx=$ the base or horizontal run of the strut, and $(l^2+l^2x^2)^{\frac{1}{2}}$ will be the length of the strut. $W\left(\frac{l^2+l^2x^2}{l}\right)^{\frac{1}{2}}$ will be the stress on the strut. Then (6)

$$V_1 = A \times \left(\frac{W\sqrt{l^2+l^2x^2}}{l}\right)^m \times \left(\frac{l\sqrt{l^2+l^2x^2}}{l}\right)^n \qquad (7)$$

$$V_1 = A \times W^m \times l_n \times \left(\frac{\sqrt{l^2+l^2x^2}}{l}\right)^m \times \left(\frac{\sqrt{l^2+l^2x^2}}{l}\right)^n$$

$$V_1 = A \times W^m \times l^n \times \left(\frac{\sqrt{l^2+l^2x^2}}{l}\right)^{m+n} \qquad (8)$$

$$V_1 = A \times W^m \times l^n \times \frac{(l^2+l^2x^2)^{\frac{m+n}{2}}}{l^{m+n}} \qquad (9)$$

From this subtracting equation (5)

$$V_1 - V = \frac{(l^2+l^2x^2)^{\frac{m+n}{2}}}{l^{m+n}} \qquad (10)$$

is the increased volume of the strut in consequence of its inclination.

But by the condition of the question V_1 gives a minimum when divided by the base (lx), that is

$$\frac{V_1}{lx} = A \times W^m \times l^n \times \frac{(l^2+l^2x^2)^{\frac{m+n}{2}}}{lx \times l^{m+n}} =$$

a minimum.

$$\frac{V_1}{lx} = \frac{A \times W^m \times l^n}{l^{(m+n+1)}} \times \frac{(l^2+l^2x^2)^{\frac{m+n}{2}}}{x}$$

Suppressing the constant value $\frac{A \times W^m \times l^n}{l^{(m+n+1)}}$ and differentiating the variable function

$$\frac{(l^2+l^2x^2)^{\frac{m+n}{2}}}{x} \cdot d\frac{(l^2+l^2x^2)^{\frac{m+n}{2}}}{x} = o$$

when the value is a *minimum*. Consequently

$$x^2 \times (m+n) \quad (l^2+l^2x^2)^{\frac{m+n}{2}-1} = (l^2+l^2x^2)^{\frac{m+n}{2}}$$

$$(m+n).x^2 = \frac{(l^2+l^2x^2)^{\frac{m+n}{2}}}{(l^2+l^2x^2)^{\frac{m+n}{2}-1}} = l^2 \times l^2x^2$$

$$(m+n).x^2 - l^2x^2 = l^2; \quad (m+n-l^2)x^2 = l^2$$

$$x^2 = \frac{l^2}{(m+n-l^2)}; \text{ and } x = \frac{l}{(m+n-l^2)^{\frac{1}{2}}}$$

Putting $l =$ *unity*. $\quad x = \frac{1}{(m+n-1)^{\frac{1}{2}}}$

Restoring the numerical value of m and n and reducing them to the decimal form

$$x = \frac{1}{\sqrt{0.5319149+1.9042552-1}} = 0.8344437,$$

which is the tangent of 39° 50½′ very nearly, and not 45° as in the case of the tie, and as the Reviewer asserts should be the angle of the strut also, if the cost for both were the same. The correct inclination of the tie when used without reference to a connecting strut is 45°, and the correct inclination of the strut, without regard to a connecting tie is 39° 50½′. But it unfortunately happens that the base of one is not a multiple of the base of the other. It is practically of great importance that all the bays of the top and bottom flanges should be of the same length. Floor beams and other laterals, of one pattern, can then be used for all the triangulations. Various other reasons can be given why the truss in this respect should be symmetrical, but they are sufficiently obvious. The cost of a strut, if made solid, will be much greater than if made hollow, but the theoretical angle of inclination will be the same in both cases.

Brevet Col. Wm. E. Merrill, U. S. Engineers, has obtained a very ingenious formula for the weight of a hollow cast iron cylindrical pillar of maximum strength for its volume. This formula is deduced from Hodgkinson's experiments. It appears to me to be very accurate, and although unpublished, I will take the liberty to use it here. It is

$$P = 0.004599558 \times W^{0.5319149} \times l^{1.9042553}$$

in which $P=$ the weight of the pillar in pounds; $W=$ the breaking weight in pounds and $l=$ the length in feet.

Suppose the height of the truss to be 45½ feet from center to center of the flanges (as in the case of the long span for St. Louis), and the panel weight 180,000 pounds. Suppose the tensile strength of a wrought iron tie is 60,000 pounds per square inch of its sectional area. A vertical tie that will just break under this load, will have a section of three square inches, and weigh $45\frac{1}{2}+3+3.38=460$ pounds, very nearly. And a tie inclined 45° will have a section of six square inches and weigh 920 pounds. In both these cases the necessary enlargement at the ends for eyes or for thread and nuts is not included. The ends of the struts will also require enlargement for similar purposes, and as this enlargement will be nearly proportional to the whole weight in both ties and braces, they may here be totally neglected.

The weight of a vertical strut $45\frac{1}{2}$ ft. long, loaded with 180,000 pounds, will be

$$P=0.004599558\times(180000)^{0.5319149}\times(45.5)^{1.9042553}=4124 \text{ pounds.}$$

If the strut be inclined to its best theoretical angle of 39° $50\frac{1}{2}'$ its length will be increased 59.26 feet, and the stress to 234,444 pounds. Its weight will be

$$P=0.004599558\times(234444)^{0.5319149}\times(59.26)^{1.9042553}=7698 \text{ pounds.}$$

By making the inclination of the strut $\frac{1}{3}$, the length will be 47.96 feet, the stress 189,737 pounds, and the weight of the strut

$$P=0.004599558\times(189737)^{0.5319149}\times(47.96)^{1.9042553}=4676 \text{ pounds.}$$

Assuming the cost of wrought iron to be double that of the same weight of cast iron, the cost of the wrought iron tie, under an inclination of 45°, may be represented by $920\times2=1840$. The cost of the vertical strut will then be represented by 4124. The combined cost of the tie and strut will be $1840+41245=964$. Calling the horizontal run of the tie = the height of the truss = unity, then the economy in this case is represented by 5964. Taking the tie at an angle of 45°, and the strut at an angle of 39° $50\frac{1}{2}'$, the economy of their combined use is

$$\frac{1840+7698}{1.834437}=5145.$$

In this case, where both the tie and strut have their theoretic angles, there is a saving of only 16 per cent. over having the strut vertical, and a saving only $\frac{1}{3}$ greater than is admitted by the Reviewer when the inclination is $\frac{1}{7}$. When the inclination of the strut is $\frac{1}{3}$, and the tie $\frac{1}{1}$, the economy of their combined use is represented by

$$\frac{1840+4676}{1\frac{1}{3}}=4812,$$

showing a saving of nearly 24 per cent. in the cost.

The pamphlet containing the description of the truss under review, also contains the description of other trusses proposed, in some of which the inclination of the strut brace is $\frac{1}{3}$, in some others it is $\frac{1}{5}$, and in others it is $\frac{1}{7}$ the height of the truss. Nowhere is it pretended that either of these inclinations is theoretically correct, but each one, under the circumstances attending its use, is *practically* the *best* that could be given it. When a tie can be used at an angle of 45°, I do not quite comprehend the philosophy of abandoning what is absolutely its best position because a contiguous strut cannot assume *its* best position also.

From the vertical to an inclination of 39° $50\frac{1}{2}'$, the cost ranges from $2\frac{1}{4}$ to $4\frac{1}{5}$ times the cost of the tie inclined 45°; of course the expression $\frac{3+x^2+2y^2}{x+y}$ does not apply to the case, and all deductions therefrom fall.

The relative cost of struts inclined at various angles, coupled with a tie at 45°, will be considerably modified by the difference that may be made between the ultimate strength and a safe working strength. If 6 be introduced as the factor of safety, the cost of the wrought-iron will be increased to six times, while that of the cast-iron will be increased to only $6^{0.53+}=2.5937$ times.

The relative cost will then be for tie 45°, and

Strut *vertical*,

$$\frac{1860\times6+4124\times2.5937}{1}=11040+10596=21636.$$

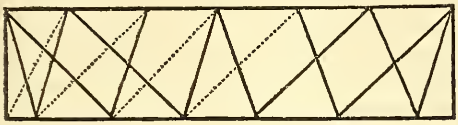
Strut inclined 39° $50\frac{1}{2}'$,

$$\frac{11040+17966}{1.83444}=\quad 15766.$$

Strut inclined $\frac{1}{3}$.

$$\frac{11040+12128}{1\frac{1}{3}}=\quad 12376.$$

That an American engineer should act upon a theory different from that long held on the other side of the Atlantic, as to the value or usefulness of counter braces (so called), seems to excite the most surprise in the mind of the Reviewer. He asks, "Upon what hypothesis are the computed strains on the counter braces based?" In answering this question reference is made to the following diagram:



The strains upon this girder resulting from the permanent load, or from one-half the weight of the bridge itself, are symmetrical about the middle point D. Of course the opposite halves are perfectly balanced, whether the girder be composed of the finest steel or of the coarsest lead. The weight of the structure may be assumed indefinitely small or indefinitely great. In either case any accidental load will disturb the balance. Let W represent a panel weight of this permanent load, whatever it may be; then the portion of the permanent load transferred to the abutments (a a') by the inclined braces will be, by

$B\,d$ and $B'\,d'$ each W, and the strain will be $W\times$ Sec. $\angle$.
$A\,c$ and $A'\,c'$ each W, and the strain will be $W\times$ Sec. $\angle$.
$A\,b$ and $A'\,b'$ each $1\frac{3}{4}W$, and the strain will be $1\frac{3}{4}W+$ Sec. $\angle$.

Under such a condition there can be no *use* for counter braces, represented by dotted lines in the left hand half of the diagram.

Now, supposing the variable or moving load, consisting of a very heavy engine, occupying the length of two panels, followed by its tender and a train of cars, be brought upon the bridge from the left—

Let $e=$ a panel weight of the engine per truss;

Let $t=$ a panel weight of the tender, and

Let $c=$ a panel weight of cars.

On arrival of the engine at b', that point receives a special load $=\frac{3}{4}\,e$, which is not balanced by a corresponding load at b. A new state of equilibrium in the truss instantly occurs. Of this additional weight $\frac{1}{12}\times\frac{3}{4}\,e=\frac{1}{16}\,e$ has been transferred to a, and $\frac{11}{12}\times\frac{3}{4}\,e=\frac{11}{16}\,e$ has been transferred to a'. The result would have been exactly the same if the train had entered from the right, only that of the special weight now at b, $\frac{1}{12}$ would be transmitted to a', and $\frac{11}{12}$ to a.

Through what channels is the transference of the lesser weight made in the two cases? It seems to me that when the moving load enters from the left, the tie $C'\,b'$ will be *used* for this purpose; but the load coming from the right, it is certain that where no tie $C\,b$ exists, it is of *no use*. How, then, when the moving load comes from the right, is the weight $\frac{1}{16}\,e$ transmitted from b to a'? Is it not *first* by tension on the strut $B\,b$; *second*, by compression on the slender tie $B\,d$; *third*, by tension on the strut $D\,d$, when having reached the centre point D, which it would also have reached by way of counter braces, it then pursues its legitimate course to a'.

How, it may be asked, supposing the strut $B\,b$ to be removed so as to close this channel of communication, is the $\frac{1}{16}\,e$ to be transmitted to a'? If the corresponding strut ($B'\,b'$) at the other end were also removed, there would obviously be a collapse. Perhaps the horizontal force $\frac{11}{48}\,e$ may contain in a latent state the transmitted weight $=\frac{1}{16}\,e$ $=\frac{3}{48}\,e$ of vertical force, which is set free on the first opportunity by reaching the next inclined member ($C\,c$). However this may all be, $\frac{1}{16}\,e$ must be transferred from b' to a', and it is not easy to conceive in what way the weight of the structure itself can influence this transference. Undoubtedly the simplest means of transferring this $\frac{1}{16}e$ from b' to a', would be by inserting a tie from b to A', but the arrangement of the parts of the girder forbids. The simplest practical means left is to insert ties tending in the desired direction.

To return to the effect of the moving load entering the bridge from the left: when the engine has reached b', $\frac{3}{4}$ of a panel weight of the engine will rest at that point, $\frac{11}{12}$ of which will be supported by the tie $A'\,b'$, and $\frac{1}{12}$ transmitted towards a. Now, if a tie exists from b' to C' tending in the direction the weight is to be transferred, and if this tie be more direct than any other inclined member, the $\frac{1}{16}\,e$ will inevitably take such route. All the ties parallel to $C'\,b'$ will be equally affected by the $\frac{1}{16}\,e$.

The partial load at $b'=\frac{3}{4}\,e$, is divided into $\frac{11}{12}\times\frac{3}{4}\,e=\frac{33}{48}\,e$, which is sustained by the tie $A'\,b'$, and $\frac{1}{12}\times\frac{3}{4}\,e=\frac{3}{48}\,e$, sustained by the tie $C'\,b'$.

The horizontal force developed in the horizontal tie $b'\,c'$ is $(\frac{1}{3}\times\frac{11}{12}-\frac{1}{12})\times\frac{3}{4}\,e=\frac{8}{48}\,e$ and in the tie $C'\,b'$ $\frac{3}{48}\,e$, assuming always that the long ties have an inclination of 45°. Then the strain on the tie ($C'\,b'$) at a certain moment is $\sqrt{2}\times\frac{3}{48}\,e$. This is a *positive* strain, and no weight or inertia of the structure can relieve it. The numerical results of this strain can be given "to the smallest fraction" when a numerical value for e is assumed. It is the *maximum* strain. It does not become *negative* because the permanent weight of the bridge acts against it, as assumed by certain writers.

The maxima of strains at any time affecting the several ties while the train passes the bridge will be—

On B' a' nothing.
On C' b' $\sqrt{2}\times(\frac{1}{12}\times\frac{3}{4}e)$.
On D c' $\sqrt{2}\times(\frac{3}{12}e+\frac{1}{12}\times\frac{3}{4}e)$.
On C d' $\sqrt{2}\times(\frac{5}{12}e+\frac{1}{2}\times\frac{3}{12}e+\frac{3}{48}t)$.
On B d $\sqrt{2}\times(W+e+\frac{3}{24}t+\frac{3}{96}c)$.
On A c $\sqrt{2}\times(W+\frac{9}{12}e+\frac{5}{12}t+\frac{15}{96}c)$.
On A b $\frac{1}{3}\sqrt{10}\times(1\frac{3}{4}W+\frac{11}{12}e+\frac{7}{12}t+\frac{15}{96}c)$.

Here it is found that the computation of the maximum strain in the several ties is a problem "capable of the most rigid solution," notwithstanding the strains on contiguous braces vary so considerably in the gross amount. When the material of these braces and of all the other parts is properly proportioned to meet the strains, the bridge may be considered in its normal condition, at least so far as the transmission of loads in the early lifetime of the bridge is concerned.

We have been informed, on the authority of such men as Eaton Hodgkinson, W. Cubit, Geo. Rennie, Henry James, Robert Willis, and Lord Wrottesley, that upon an iron bridge of 48 feet span an engine and tender weighing 39 tons, at a speed of 50 miles per hour, in consequence of the bridge having a static deflection of $\frac{1}{5}$ inch, the speed increased the deflection $\frac{1}{7}$, or to what would be due to a weight of about 45 tons. If, then, a slight static deflection causes the moving load, under a velocity that is not unusual, "to exercise the same pressure as if it had been increased by $\frac{1}{7}$, and placed at rest upon the centre of the bridge," I do not see, with the Reviewer, that "an inch more or less is a matter of no moment at all in the deflection."

The maximum variable load carried by the tie B' d' and by the strut B' b' is $(e+\frac{3}{24}t+\frac{3}{96}c)$.

Under this variable load more or less deflection occurs at b'. If, now, the tie B' a' be inserted and screwed up to the slightest degree of initial tension, not so as to increase the pressure on the strut, when the engine passes off the bridge, the strut B' b' must remain under the same pressure as before, in consequence of its reaction on the tie B' a'.

Bringing the engine back to d', the tie B' d' is again loaded, and the tie B' a' relieved. No change in the deflection at b', nor difference in the pressure on the strut has occurred. On this principle the strains on the counter braces for the bridge at St. Louis were computed. If it were possible to construct a bridge perfectly level and straight, so that it would have no static deflection, whether loaded or unloaded, its dynamic deflection, however great the speed, must be very little.

In calculating the strains upon the St. Louis bridge, the moving load was not considered as uniformly distributed, consequently the maximum strains on the flanges do not occur at the middle of the span. Hence, $28\times61635=1.725780$ pounds, is not the correct maximum strain on the top flange. It cannot, therefore, be fairly inferred from such a calculation that some initial strain is assumed on the counter braces when the bridge is fully loaded, nor that the condition is such as "involves the provision of greater strength in the diagonal struts and ties than is absolutely required for the useful duty they have to perform."

STEEP RAILWAY GRADIENTS.

At the present time, when attention is being again directed to the unsatisfactary working of the Mont Cenis engines with their horizontal gripping wheels and attendant complications, it is worthy of note that during the construction of the Ottoman railway, Mr. T. R. Crampton made regular use of, and worked by an ordinary contractor's engine, a tramway laid for a length of 800 yards to a gradient of one in eleven. This tramway was altogether about a mile long, and for 800 yards of this length it rose, as we have said, at an inclination of one in eleven, afterwards descending for about the same distance with inclines of one in fifteen and one in twenty. About 200 yards of the gradient of one in eleven consisted of curves of 400 feet radius. The tramway was employed for the conveyance of materials to be used in the construction of the main lines, and during six months about 10,000 tons were carried over it. It was worked by an ordinary contractor's locomotive, built by Mr. Hughes, of Loughborough; this engine having cylinders eleven inches in diameter by eighteen-inch stroke, and two pairs of coupled wheels two feet six inches in diameter, placed four feet six inches apart from centre to centre. The weight of the engine in working order was ten tons, and it drew behind it a load of thirteen tons up the gradient of one in eleven. The pressure of the steam was from 90 pounds to 100 pounds per square inch.

On an incline of one in eleven, the resistance due to gravity would be 203.64 pounds per ton, and taking the engine friction at eighteen pounds per ton, and the wagon friction at ten pounds per ton, we have the following total resistance to be overcome by the engine in ascending the gradient:

	Pounds.
Resistance due to gravity: 23 tons at 203.63 lb. per ton	4,683.5
Engine friction: 10 tons at 18 lb. per ton ..	180
Wagon friction: 13 tons at 10 lb. per ton ..	130
Total	4,993.5

or, say, 5,000 pounds. The weight available for adhesion was ten tons, or 22,400 pounds, which would be diminished by one-eleventh on an incline of one in eleven. The actual adhesion weight available in the incline would, therefore, be—

$$22{,}400-\frac{22{,}400}{11}=20{,}364 \text{ lb.},$$

and the adhesion must, therefore, have amounted to very nearly one-fourth of the load on the wheels. An engine of the dimensions above given would develop a tractive force of—

$$\frac{11^2\times 1.5}{2.5}=\frac{121.\times 1.5}{2.5}=72.6 \text{ lb.},$$

for each pound of effective pressure per square inch on the pistons; and to overcome the tractive pressure of 5,000 pounds, this effective pressure must thus have been $\frac{5{,}000}{726}=68.6$ lb. per square inch. This pressure on the piston could, of course, readily be maintained by a boiler pressure of 90 pounds per square inch.—*Engineering.*

Roman Mortar.—The Roman mortars were essentially different from ours; they were composed, with a few exceptions, of pure lime mixed in large proportions with fragments of bricks coarsely pounded. This mortar formed the bottom and side lining of cisterns, fish-ponds, aqueducts, &c. Probably the introduction of the dry substances was for the purpose of hastening the solidification by exhausting the superabundance of water from the lime. Thus, probably, the desiccation of the mortar was obtained and its compactness and impermeability to water secured. The lime, sand, and brick of these mortars were those of the country where the structures into whose composition they enter now exist.

PHOTOGRAPHY.

PICTURES OF THE ECLIPSE—PERMANENT PHOTOGRAPHS.

From the "Mechanics' Magazine."

The total eclipse of the sun, visible last August in equatorial Asia, has called special attention to astronomical photography, and this branch of the science will doubtless be considerably improved before it is brought to bear next August upon another total eclipse, visible throughout a large portion of the United States. The recent photographic operations of the English expedition to India proved a failure, because of the want of a skilled photographer upon the staff. The plates were spoilt, because of the drying of the silver solution upon their surfaces, and they were all under-exposed. The first of these mishaps may always be avoided, and the German expedition at Aden avoided the latter by trying some experimental plate shortly before the totality, to get some clue beforehand to the decline in the actinism of the light produced by the eclipse. Next year, more pictures may be obtained in the same space of time, by adopting the plan of the Germans at Aden, of taking two pictures of the eclipse upon one glass plate. This is done by a simple plan well known to photographers. The sliding dark back, carrying the plate, is lengthened, so that after one picture is taken, and the light cut off, the slide is moved onwards two or three inches, and another picture taken upon the same film. This plan saves half a minute, or more, which otherwise would be lost in changing the slides.

The English apparatus worked capitally during the eclipse, but even in this the German expedition had one slight improvement. The photographic part of their apparatus was not directly fixed to the tube of the telescope, lest the necessary motions of the slides should set up vibrations, so the connection was made by means of an india-rubber tube, which also excluded all stray light. In ordinary photographic operations, if the operator desires to get the maximum number of negatives in the shortest space of time, he not only furnishes his camera with a long sliding back, but he increases the number of his lenses, to throw several similar pictures upon different parts of the same sensitive plate. This raises the question whether in photographing solar eclipses it may not be possible to mount two or three reflectors or refractors at the end of a single telescopic tube, so that, say, three pictures are thrown at once upon the plate in a vertical line one above the other. Then, by shifting the plate as already described, six pictures would be obtained upon one film; or, by a second motion of the plate, even as many as nine might be impressed.

Many plans for increasing the permanency of photographic prints have been under consideration at the various societies during the past year, but the results, as regards pictures upon albumenized paper, have been small. The very few photographers who are really scientific men, turn out silver prints which in comparison with the general run of such pictures, are stable, fresh and good, hypo-sulphite of soda solution, and thorough washing of the prints after fixing, being the best guarantees of permanency. After the washing and mounting of such pictures, rolling and waxing seems to increase the stability, by the production of a print with a hard glazed surface, somewhat protected by the wax from deleterious impurities in the air. But no care in silver printing upon albumenized paper seems to give security against fading in the long run, and no photographic chemist of eminence would risk his reputation by the assertion that any such silver pictures are as durable as engravings in printing ink. Messrs. Disderi, Johnson, and others, have been producing some very delicate and beautiful prints upon wet collodion, which prints were afterwards transferred to paper. Little or nothing is as yet practically known about the durability of these pictures, but theoretically there are reasons for supposing that they will last longer than the common kind. At all events, they are more pleasing and engraving-like in appearance, and can be turned out at the same price as their better-known rivals.

Carbon was the basis of the best and most imperishable of the inks in use by the monks of old, and there is no doubt that the most permanent photographic pictures at present obtainable upon paper are those produced by the carbon process. Mr. Joseph Swan first produced these pictures upon a commercial scale, and after working the process up to a great state of perfection, he recently sold his patent for a high sum to a London Company, but there is scarcely a phhotographer in London who will undertake to supply carbon portraits on any terms whatever. One of the best and certainly one of the most beautiful kinds of permanent photographic pictures are transparencies upon collodion, cemented between two sheets of glass with Canada balsam. The balsam in its natural state will not do, as the essential oil it contains gradually evaporates, and at last the picture ceases at places to remain in optical contact with the glass. This essential oil should first be driven off by heat to such an extent that the balsam hardens as it cools, and this hardened balsam should be used in cementation processes. Even this, in some cases, tends to become brittle with age, whereby the plates have a liability to split asunder too easily, so that experiments are desirable to ascertain the best substance to mix with the balsam to increase its toughness.

This question of durability of photographs is of far more national interest than is apparent at first sight. If photography had been known in the days of Queen Elizabeth, and the photographers of that time took nothing but fading pictures, so that that the London life of the period was thereby pictorially lost to us for ever, except in the imperfect wood cut and flattered oil portrait, what censure we should now heap upon the photographers of old. Yet the photographers of to-day stand a good chance of falling into similar disrepute in the opinion of posterity. Month by month the physical features of all our cities are changing with great rapidity. Railways are cutting up the old streets and new streets are being cut through in all directions. Little is thought of these changes at the time they are made, but after the lapse of a few years, accurate pictures of our cities as they used to be, will begin to grow in public interest.

THE BESSEMER PROCESS.

PIG IRON—BLAST AND BLAST PIPES—RECARBURIZER.

From "Engineering."

In the practical management of a Bessemer steelworks the selection of pig iron is one of the most important questions. It is well known that the percentages of silicon, carbon, manganese, sulphur, phosphorus, and copper, must all correspond to certain figures ascertained by experience, or must at least remain within certain very narrow limits, in order to insure a complete reliability and regularity of practice and a high quality of the metal produced. The percentage of silicon should not be below 1 per cent., and not above 2 per cent.; the percentage of carbon should never be below 3 per cent., but ought to be as high as possible. The presence of manganese to a certain extent replaces that of carbon; but the pig iron charges should not contain more than 3 per cent. of manganese, because the great affinity of manganese for oxygen causes a very violent action in the converter, resembling a series of explosions, by which a great quantity of metal is thrown out of the vessels. Silicon is an antidote against this violent action of manganese, and a charge of manganesic pig iron, mixed with a suitable proportion of pig iron, containing about 3 per cent., or 3.5 per cent. of silicon, works quietly, and gives an excellent product. In a similar manner it is a very advantageous practice to mix pig iron which is overcharged with silicon with a proportionate quantity of spiegeleisen in making up the charge for the converter. The charge requires at least 2 per cent. of manganese for every per cent. of silicon which it holds in excess of the requisite quantity, say 1½ per cent. When the pig iron is melted in an air furnace the percentages of carbon, silicon, and manganese are sensibly diminished by the ordinary influence of the flame; this effect, to a certain extent, depends upon the management of the melting furnace, and the attention of the operator should be directed to the prevention of an excessive oxidation in the air furnace. When a cupola is used for melting the pig, or when the pig iron is run direct from the blast furnace into the converter, the proportionate quantities of carbon, silicon, and manganese named above may be slightly reduced.

The distinction which is made between combined and uncombined or graphitic carbon, when judging of the applicability of pig iron for the Bessemer process, is a prejudice. The total percentage of carbon, both combined and uncombined, is the only criterion, as far as the applicability to the Bessemer process is concerned. Sulphur, phosphorus, and copper are limited to the extremely small percentage of 0.05 per cent. whenever a high quality of metal is to be produced. From this it does not, however, follow that no pig iron which contains a higher percentage of either of those three impurities can be employed with advantage. By mixing different kinds of pig iron in a judicious manner, it is possible to dilute the impurities, and bring them down to the normal percentages. In making up a charge from three different kinds of pig iron, for instance, one-third of the charge holding 0.15 per cent. of sulphur, the second contaminated with phosphorus to the same extent, 0.15 per cent., and the third part of the charge containing 0.15 per cent. copper, it is obvious that the mixture of liquid iron charged into the converter comes within the limits named above, and is perfectly suitable for the production of the best qualities of Bessemer metal, although none of the classes of pigs from which that charge was made up could have been by itself employed for the Bessemer process.

The pig iron, when selected and made up into a charge, should be melted rapidly, and at the highest temperature which can be produced. The runners or channels through which the iron passes into the converter must be of large sectional area, and carefully dried and heated previous to tapping. The converter must have a full white heat before receiving the charge, and the liquid iron must be run into it as rapidly as is compatible with safety and cleanliness. The converter should never be turned up before the safety valve upon the air vessel has commenced to blow off, and the blast is let on full before the converter is brought into an upright position. The liquid column of iron in the converter is from 12 to 14 in. deep. This depth is not exceeded in the converters of larger sizes, which have a larger diameter and a correspondingly greater number of tuyeres, so as to hold the greater quantity of metal without increasing the depth of the ferrostatic column. The blast pressure in the air vessel varies from 12 to 25lb. on the square inch, and it is never less than three times as great as the weight of the liquid column which rests upon the tuyeres. This shows that the back pressure caused by the liquid column bears only a comparatively small proportion to the total sum of resistance presented to the passage of the blast through the Bessemer apparatus.

The resistance which the blast must overcome in passing through the converter is made up, first, of the friction and other loss of power in the pipes and passages between the air vessel and the tuyere box; second, of the friction and resistance caused by the numerous and narrow holes of the tuyeres; third, of the head of liquid column covering the tuyeres and the friction within the liquid metal; and fourth, of the friction and resistance caused by the contracted flue or mouth of the converter. The sum total of these resistances offered to the blast in passing through the vessel is measured by the pressure gauge, on the platform, and it is obvious therefore that the variations of pressure, as indicated by the gauge, do not of themselves show to which particular item any fluctuations are due. The burning and shortening of the tuyeres may lessen the friction, or the partial choking reduce the area of passage; the iron may become more or less fluid; the throat may be partly filled with slags, and thereby reduced in area; or a leak in the pipes may cause a loss of air pressure: all these and many other causes, which by their simultaneous action interfere with each other's individual effects upon the pressure gauge, make the indication of that instrument more or less confused and difficult to understand. It is preferable to look to the behavior of the converter instead of to the indications of the pressure gauge in controlling the blast pressure during the charge. The speed of the gaseous current must be so great that the flame which rushes out of the converter maintains a clear and well defined outline and a steady position. If the flame begins to waver or oscillate laterally, it is always considered as a sign of insufficient blast pressure. An excess of blast pressure is attended with violent and very voluminous eruptions of slag and metal from the vessel, and it can be easily remedied by allowing a portion of the blast to escape from the main pipe. This is preferable to throttling, because it does not throw any sudden back pressure upon the blowing engine, and allows the latter to keep up its speed with uniformity. An accident which occasionally happens in blowing a Bessemer charge is the cracking of a tuyere. If this takes place during the earlier part of the process the vessel may be safely turned down, and the metal will remain fluid while a fresh tuyere is inserted. If the accident happens during the later stage of decarburization the danger of setting or solidifying is much greater, but there is still a possibility left to to save the charge by skilful management. The vessel is turned down for a second, and this allows the liquid steel which fills the crevices of the cracked tuyere to solidify, and choke the escape passage or leak. The vessel is then tight for another minute or half of a minute, after which time the process must be repeated. It is possible to repeat such an operation three of four times, and the few fractions of minutes thus gained may be sufficient for completing conversion of the charge.*

The most important and at the same time the most difficult part in the management of a Bessemer charge, is the determination of the precise moment when the charge is completed, and where the vessel must be turned down for receiving the final dose of spiegeleisen. When the flame is clearly visible at the end of the charge, there is no difficulty in recognising a sudden change of its color and appearance after a short practice; but some qualities of iron evolve such masses of dense smoke of red, white, brown, or yellow color, that the flame is completely covered, and the changes in it are very difficult to observe. The spectroscope, the slag-test, and similar other contrivances, are then brought into requisition with more or less success; but fortunately these inconvenient kinds of iron form the exception, and not the rule, amongst the pig iron which is applicable to the Bessemer process.*

The purpose and intention of the final addition of spiegeleisen is to remove the surplus oxygen from the metal which may have remained in it after complete decarburization. The elements by which we can remove oxygen from iron are carbon, silicon, and manganese. Of these silicon has the important advantage that it forms no gaseous combination with oxygen, and therefore causes no ebullition in the ladle and in the moulds. Against this there is the great danger of overcharging the steel with the silicon, which may be added to it in excess of the precise quantity required for the removal of the oxygen. The consequence of such an overcharge would be hardness, brittleness, and want of elasticity in the steel produced. Carbon and manganese form gaseous combinations with oxygen at the high temperature existing in the converter; the ebullition in the ladle and moulds is therefore not easily avoided when these elements are used for removing the oxygen, but the surplus of carbon left gives

---

* The giving way of the lining around a tuyere or the burning away of a tuyere, are of more frequent occurrence. We have seen a four ton vessel turned down 55 minutes within five minutes of the completion of the blowing, and the charge saved, but of course very cold, and sculling in the vessel and ladle. We have turned down nine times within fifteen minutes, and saved the charge. If the metal runs through a small hole, and sufficient *time* is taken to chill it in the hole, a charge may be generally saved. But the forcing up of a wet bottom by the steam formed in it, and any large hole in a thin part of the lining, are remediless cases. The metal in the converter must then be cast into pigs, if possible, as if partially blown it will stick to and destroy the cast iron ingot moulds.—Ed. Van Nostrand's Magazine.

* But one of some hundred kinds of pig iron with which we have experimented in this country, has given an uncertain indication of decarburization.—Ed. Van Nostrand's Magazine.

the required hardness to the steel, and any surplus of manganese remaining in the steel is comparatively harmless as regards the quality of the product. When silicon is present the manganese is less liable to cause ebullition, since it can form a liquid slag, or silicate of manganese. For these reasons the final addition to the Bessemer charge should contain the three elements, carbon, silicon, and manganese. There should be a surplus of manganese to allow for the uncertainties regarding the quantity of oxygen left in each charge; there should be no more silicon than is required to form a slag with the greater portion of the oxide of manganese; and there should be no more carbon than is needed for finally carburizing the charge of steel. The natural spiegeleisen, as a rule, is too poor in manganese, and too rich in carbon to produce this effect, and when steel is made by its application it is difficult to produce a very soft quality. Mr. Henderson's ferro-manganese, which contains from 20 to 30 per cent. of manganese combined with 5 per cent. of carbon and a small quantity of silicon, is a substance of much greater value for the production of the highest qualities of soft steel; and the mode of manufacturing such artificial alloys affords a possiblity of bringing the relative quantities of the elements to almost any desired proportion.

The spiegeleisen should not be kept in the furnace for any length of time, as it loses its manganese and silicon by oxidation. It should run into the converter with great speed, so as to enter into the liquid charge with a certain momentum. This prevents its collecting upon the surface of the decarburized iron, which has a greater specific gravity than spiegeleisen or ferro-manganese. It is not necessary to turn up the converter a second time after the final addition, since an immediate reaction takes place, and a large white flame rushes out of the converter although the blast is entirely shut off. The liquid steel is then immediately poured into the ingot moulds. Only in the exceptional case, when there in no flame visible at the converter mouth after the addition of manganese, the vessel must be turned up a second time, and the blast passed through it for a few seconds. This is done because the absence of a vivid reaction indicates that the charge had not been blown long enough at first, so that there was no surplus oxygen left in it, and the additional time of blowing is required for removing the surplus of deoxidizing elements added at the end of the charge.

CHEAPER RAILWAYS AND WORKING.

The British newspapers, professional and commercial, are discussing this subject very earnestly. It is important to us in America, however, that we should not be led astray by names. The cheap and light railways advocated by Englishmen, are by no means to be deprived of the best known systems of drainage, ballasting, rails, rail jointing, rolling stock and power. Indeed, it is proposed to increase the weight of rails, and a great economy is expected from articulating engines and trains at a considerable extra cost. British engineers propose to cheapen railway construction chiefly by *avoiding heavy earthworks and costly works of art, and by filling the trains.* It is proposed to go over and around hills rather than through them. The cost of steam power on gradients and of wear and tear on curves, is less than the interest on the works necessary to avoid gradients and curves, within reasonable limits. The American system may be followed to advantage, in this particular.

But in respect of stations, the American system is equally wrong—in the other direction. Our traveling public is incommoded, disgusted and led to avoid railways rather than accommodated and encouraged to travel by them. A railway station need not be a palace, but Paddington stations at West Philadelphia, Albany and Baltimore, for instance, and a St. Pancras in the upper part of New York, with overhead or underground downtown branches, would pay better than the cramped disagreeable and unsafe sheds that now incommode the great traffic of these localities. In the matter of carrying tons of non-paying load to pounds of paying load, the English system of compartments, and guards paid to keep them empty,* is as bad as possible. Now that our own system of one fare and one class thoughout is modified by the introduction of sleeping berths, sitting-rooms and other accommodations specially (and roundly) paid for, it may well be studied abroad. The transportation of non-paying load however, is a very serious evil everywhere; there is no really good practice to copy, and the whole department requires reorganizing on a radically new plan. The following considerations on this subject

* English express trains are very heavy, very fast, and very frequent, and they are rarely well filled. A few shillings to the guards and porters will purchase accommodations that cost the railway company many times that amount.

are compiled from various numbers of "Engineering" and from the "Railway News":

Railway transport in itself is a very profitable business, yielding from 50 to 60 per cent. of gross receipts in the shape of profits. These handsome profits have, however, been rarely if ever realized for the benefit of those who have invested in the undertakings, for previous to the distribution taking place a host of parasites have to be provided for. The seven lean kine which eat up so large a share of the profits of railways are: Unnecessary expenditure in preliminary and parliamentary proceedings; excessive payments for land; excessive cost of construction; unremunerative expenditure upon branches; duplicate lines and improvements upon original line by short cuts and otherwise; cost of financing and jobbery connected with formation of company, issues of securities, and construction contracts; and accumulations against capital account of dividends paid, but not fairly earned. By way of illustration in a line now being constructed by the Midland Company, running parallel with a line belonging to the Great Western, there is no difference whatever in the formation or the nature of the work; but the same length of line which cost the Great Western Company one million is now being constructed by contractors for two hundred thousand pounds, or just one fifth! In the case of the Brighton Company, the committee of investigation specified twelve branches which did not pay working expenses, much less any return for interest on capital.

The interests of a small community of shareholders and bondholders, who have wasted their money in a railway are not to be considered against those of many millions of people who are made to pay for the waste. Were every corn-mill and every bakery in the kingdom built of such costly materials, and of such needless dimensions and such elaborate architecture, as to have cost twice what it ought, this would be no excuse to the public for demanding of them twice the present price of bread. For all the great necessaries of life—food, drink, clothing, firing, lighting, the means of transport, etc., the necessary cost of which is known—the public will demand and ultimately enforce the supply at that cost, including a fair profit upon only the *necessary* capital employed.

It has been too long the habit to regard the mere cost of traction as the chief element of railway expenditure, whereas *the* great item of expense is interest upon capital—not of course that interest or dividend is always paid, although it is not the less chargeable in default of payment. To pay the interest on the whole cost of the present lines requires a charge in the way of fares and freights at least twice greater than the present total working expenses. Of the latter, locomotive power, repairs and renewals of rolling stock, and maintenance of way, which alone are influenced by gradients and curves, do not form much more than one-half, the remainder going in management, train and station service, rates, taxes, Government duty, etc. In other words, nearly or quite three-fourths of what the public now pay to the railways is absorbed in expenses and in payments upon capital not in themselves influenced by the steepness of gradients or the sharpness of curves. Again, taking the expenses which are so influenced, it is certain that very considerably steeper gradients and shorter curves may be introduced, here and there, to save costly works, without increasing the cost of locomotive power and the outlay for wear and tear by more than a very moderate percentage. If this increase did not, as it hardly would, exceed five per cent., and the new line cost but half as much per mile as the old, then for every pound now paid by the passenger, very nearly five shillings would be saved to him while paying the same rate per cent. of profit upon the railway capital as now. If, by the outlay of £1,000, a clear saving of £50 can be effected yearly in working expenses, the outlay is justifiable, but if £100,000 are spent to obtain theoretically favorable gradients or curves which do not really save £1,000 yearly in working expenses the outlay is a wasteful one If this extra outlay be made upon a single mile of line, as upon a costly viaduct, or a tunnel, the interest upon it at five per cent. is 1,200,000 pence per annum, equal to £13 14s. per day, and equal to nearly 7s. per train for each of forty trains running daily over that mile for 365 days in the year. Taking the number of trains at a more reasonable figure, say, twenty daily in both directions, it is evident enough that the cost of working a comparatively steep incline half a mile long, the adoption of which would avoid the necessity for a costly tunnel or viaduct, could be nothing like 14s. per train above and beyond the necessary cost of working a level.

SEWAGE.

OLD AND NEW SYSTEMS—REQUIREMENTS, CAPACITY AND VENTILATION OF SEWERS — APPLICATION OF SEWAGE TO AGRICULTURE—PURIFICATION OF SEWAGE.

Compiled from M. Mille's account of the Paris Sewage, Chief Engineer Hermany's report on Memphis Water Works, "The Engineer," "The Builder," The report of Messrs. Bateman and Bazalgette on the Glasgow Sewage, &c.

The complete removal of sewage, not only from towns, but from the waters and even from the vicinity of large towns, is one of the most vital and urgent questions of the day. The health of millions and the lives of thousands of human beings depends upon it. In the older towns of Europe, it is perhaps the foremost engineering as well as sanitary problem. In the larger American towns, especially those that are not traversed or surrounded by great volumes of natural tides or currents to dissipate and dilute the sewage, the necessity of disposing of it by artificial means is felt and acknowledged. But unlike the greater number of works for the public protection, such as fortifications, docks, fire departments, &c., which return no revenue, sewage works properly constructed, are *commercial and manufacturing investments*, as much so as the importation of guano or the preparation of the Charleston phosphates. Besides being indispensable to the healthfulness of all towns, and even the habitableness of some, sewage works may be made to pay directly, in the wonderfully increased productiveness of lands to which the refuse matter is applied. Even in cities like New York, this view of the case cannot long be ignored. Although New York is surrounded by a volume of water that dilutes and appears to dispose of its sewage, great banks of this material are already found in all its slips and beneath its waters—foul banks that are even now reservoirs of disease, and will one day spread pestilence along its shores, instead of directly contributing to its health and wealth, by cheapening and so bettering the food of its people.

Ancient Systems.—In ancient Rome the *cloaca maxima* carried the whole refuse liquids of the city into the Tiber, as was the case with the Thames not long since. The Arabs introduced irrigation into Europe, and the practice spread gradually along the western coast of the Mediterranean. In the thirteenth century, at the time of the Christian conquest, the plain of Valence was watered by seven branches of the Xucar, and in the town the sewage of the houses was conveyed through earthen pipes, or brick conduits, into open sewers. As the population increased infection became serious, and the conqueror, Don Jayne d'Aragon, ordered that the waters of a canal called the Cuart should be made to run into the sewers for two hours in every twenty-four, to carry off the filth. Near the walls of the town the inhabitants drew out the mud, and, after drying it in the sun, used it as manure, while those who lived further down dammed the stream, and forced the water to pass into ditches in their own fields. The result was that the portion of the Huerta de Valence which lay nearest to the canal became a perfect marvel of fruitfulness, and remains so to the present day. In Milan, in the middle ages, the sewage of the town, and the refuse of the woolen works, were received in open sewers, which surrounded the town, and the contents were carried to the river Po by means of an old bed called the Vettabia, which traversed the lands of the Abbey of Clairvaux, belonging to the monks of Citeau. Tradition says that it was Saint Bernard himself who conceived the idea of feeding the abbey lands with the foul waters of this stream, and that the result of his experiment was marvellous. In the fifteenth century Francois Sfforza cut the canal of the Mortesana, and appropriated the water of the Adda for the cleaning of the sewers of Milan. The irrigation was then extended over between three and four thousand acres; and this, with the great industry of the people of Lombardy, created the *marcites*—meadows which yielded in some cases as many as eight crops in the year, supported more than three milch cows on every hectare (two-and-a-half acres), and gave rise to the famous manufacturo of Parmesan cheese.

Modern Systems.—In London and some other cities, the sewers were originally intended to carry off rain water only. Up to the year 1815 it was penal to discharge sewage or other offensive matter into the sewers; cess-pools were regarded as the proper receptacles for house drainage. But as the population increased, tho subsoil became thickly studded with cess-pools, improved household appliances were introduced, overflow drains from the cess-pools to the sewers were constructed; thus the sewers became polluted, and covered brick channels were necessarily substituted for existing open streams. In the year 1847 the first act was obtained, making it compulsory to drain houses into sewers. The present English solution of the problem, as developed in their general systems of town drainage, has been to construct underground, generally along the center lines of streets and alleys traversing the districts to be relieved, conduits of masonry; or to lay stone-ware pipes. Into these all house and factory refuse, and all cast-off matter which can be floated, are conducted by means of branch drains and street gulleys, and by the aid of an ample public water supply and occasional rainfalls, through these conduits into natural watercourses, to be diluted so far as to be inoffensive. This manner of disposing of city sewage is called the *water-carriage* system. It is, with some exceptions, the general practice in England; and, so far as sewage works have been designed and constructed in the United States, the universal practice.

In cases where there is insufficient fall from the street sewers to the place of deposit, pumping is largely resorted to; the whole of the vast low level drainage of London, amounting to more than 83 square miles, is thus disposed of. The cities of Liverpool, of Leamington, the proposed immense drainage of Glasgow, besides numerous great cities on the continent, like Berlin and Hamburgh, have works conceived and executed with the same view. Similar works are proposed for some of the American cities; Troy among others.

The mixing of fecal matter with water, and disposing of it through the sewers, finds, however, little favor on the continent of Europe, and is obliged to encounter much opposition from some of the ablest scientists and engineers in England. It is condemned on account of polluting the natural watercourses and depriving agriculture of a valuable fertilizer. The tides of the ocean, even, are proved inadequate to remove the sewage cast into it. The expectations respecting the transporting action of the tide have proved completety delusive, as the blackened foreshores of Erith and Greenhithe, and other places on the Thames, can testify. Any town that discharges its sewage into the sea, or gets rid of it, as the usual term is, by this method, will find that there is a vast difference between a simple transference and a complete removal. Absorption, not solution nor dilution, is the only manner in which to effect the complete removal of sewage, and that is a faculty enjoyed in the fullest degree only by the soil and the wonderful assimilating action of plants. To avoid the nuisance and the waste of throwing the sewage into streams or the sea, the fertilizing matter must either be kept out of the sewers altogether, and a different system of collecting and transporting it devised, or else it must be collected at the outflow point of the system. It may in either case be deodorized, should that process prove successful. The main drainage of London is intended to float or propel by running water, all the sewage of the town, to a point far below the town, where the fertilizing matter will be collected in solid form. The Paris system is the same, and has been frequently described. During the last twenty years, a complete system of drainage, terminating in a main sewer with a flow of from three feet to six feet per second has been attained, and the authorities have finally determined that the Seine should be cleared of the pollutions of the town. In Paris, however, the use of cess-pools continues to a great extent, and the foul matter of the houses is not in all cases passed into the sewers. But the cesspools are properly cared for and cleaned. But this is an expensive process. Over 2,000 tons per night are removed from private houses. Steam pumps convey over 500,000 tons per year to the basins at Bondy, six miles from Paris, and 50,000 tons of half-solid matter which the pumps will not act upon, is removed in casks. At Bondy the night-soil is transformed into sulphate of ammonia, and into *poudrette*, which is the solid deposit left in the basins, dried and sifted. But this method of preparation is very rude, and nineteen-twentieths of the useful matter are said to be lost.

In many American towns, however, the only system that can be *afforded* at present, is simply to get the sewage out of the town, by the comparatively inexpensive method of water carriage in the sewers. In the Memphis region, for instance, where this subject has come up for settlement, the land for agricultural purposes is too cheap, abundant, and fertile, and the scope of agriculture too limited to permit the expensive application of fecal matter as manure; and the further pollution of the Mississippi by the addition of the sewage from another city is a contingency altogether too remote for serious consideration.

Requirements and Capacity of Sewage Works.—To what extent any system of drainage should be a modification or a suspersedure of the natural drainage, depends on the topography, area, natural streams of running water, rainfall, and population which obtain in different districts or cities. The best existing systems of artificial drainage give evidence of having arrived at whatever degree of perfection they now possess by passing successively through the stages of improvement, and at least partial supersedure of the originally existing natural drainage. In some of the most densely populated cities the only traces of a former natural drainage are the lines of the main outfalls, which, to a greater or less degree, coincide with the natural lines of rain-water outfalls. Therefore, it is evident that the tendency of all systems of artificial drainage is inevitably in the direction of the *total supersedure of the natural drainage.*

The first question to be solved is the size of the sewers; to determine which, three elements are indispensable; the areas to be drained, the inclination of the sewers, and the maximum quantity of sewage and rain-water discharged in a given time from said areas. The first two of these elements only are known; the latter remains to be determined, and is composed, in cities enjoying a public water supply, in connection with a general use of modern house conveniences, of the *refuse water* holding the solid matter in suspension, and the *rainfall discharge.* The refuse water is found, in densely populated cities, to vary but inappreciably from the water supply in bulk; one-half of which, according to observations on the London sewers, finds its way to the sewers in six hours, and the other half in the eighteen remaining hours out of the twenty-four. Then, taking the water supply at 60 gallons or 8.0214 cubic feet per 24 hours *per capita*, and the resulting sewage as the same in bulk, one-half of which being discharged in six hours, and rating the ultimate population at seventy-eight persons to the acre, equivalent to fifty thousand per square mile, there will result 0.0144 cubic feet as the sewage per acre per second (equivalent to a rainfall 0.0143 in. in depth per hour), rated according to population and water supply. The rainfall discharge depends upon the depth of rain falling in a given time, and the condition of the surface upon which it falls, whether dry, wet, frozen, paved, built over, or cultivated; modified by the declivity of the slopes along which the discharge takes place. Mr. Bazalgette's paper on the London Main Drainage, says: From careful observations of the quantity of rain falling on the metropolis, within short periods of time, it has been ascertained that there are about 155 days per annum upon which rain falls; of these there are only about 25 upon which the quantity amounts to $\frac{1}{4}$ of an inch in depth in 24 hours, or the 0.01 part of an inch per hour if spread over an entire day. Of such rain-falls a large portion is evaporated or absorbed, and either does not pass through the sewers, or does not reach them until long after the rain has ceased. In the report of Messrs. Bidder, Hawksley and Bazalgette, in 1858, on the subject, it is stated that continuous observations, show that the quantity of rain which flowed off by the sewers was, in all, cases, much less than the quantity which fell on the ground; and although the variations of atmospheric phenomena are far too great to allow any philosophical proportions to be established between the rainfall and the sewer-flow, yet they feel warranted in concluding, as a rule of averages, that $\frac{1}{4}$ of an inch of rainfall will not contribute more than $\frac{1}{8}$ of an inch to the sewers, nor a fall of 0.4 of an inch more than $\frac{1}{4}$ of an inch. Indeed, they have observed rainfalls of very sensible amounts failing to contribute any distinguishable quantity to the sewers. But there are in almost every year exceptional cases of heavy and violent rain-storms, and these have measured one inch and sometimes even two inches in an hour.

As to the size of sewers, in Great Britain and on the continent, experience has demonstrated that improper substances admitted into sewers will obstruct them, no matter what may be their dimensions, and must be removed by manual labor. To effectually meet this evil, the earlier practice was to make all the sewers large enough to conveniently admit men, to pass through them and remove matter which should never have found its way into them. Sewers constructed upon this plan are costly to build and keep clean; they induce the admission of refuse which cannot be removed by water, but which could generally be carted away much more economically from the surface at the points of accumulation than by being first unwisely forced into sewers, thence exhumed by the tedious and life-destructive labor of the sewer-scavenger, and then carted away; calling into requisition a "description of labor which it is improper for human beings to perform, and which ought to be forbidden, as being false in principle, and belonging to a low state of art, and as being ignorant or interested excuses for the avoidance of the trouble and expense of practicable and efficient substitutes." As sanitary measures, large sewers are very objectionable. The constant accumulation of foul matter during the dry season of each year, when the flow of sewage does not keep the main sewers clean, would convert them into elongated cess-pools, and thus originate or aid in prolonging epidemics to a fearful extent. To keep sewers of this magnitude clean, by flushing them with water from the public water supply, would involve an expense for elevating water for this purpose alone, which at present cannot be estimated; except in very flat districts, it appears preferable to provide for the removal of excessive rainfalls, by natural drainage, or by surface drainage, and to provide only for the ordinary quantity in the underground system. The main sewers of the Memphis works are designed, when running full, to discharge three times the maximum quantity of sewage independent of rain-water, or three times 0.0144 cubic feet per acre per second, as heretofore determined; *i. e.*, the sewers are made sufficiently large to carry into the river sewage equal in volume to a discharge of one inch of rain in 24 hours. The minimum inclination of the main sewers is to be 3.168 feet per mile, which, in the case of a three-feet sewer, when running half full, will produce a velocity of current equal to 2.6 feet per second, or 1.4 miles per hour, calculated by Prony's formula. The actual velocity, however, in a sewer of this size and inclination, when half filled, is greater from the fact that at every junction with its branches (provided the junctions are properly made) the volume of sewage flowing in the main sewer receives an increment of velocity arising from the greater inclination of the branch sewers.

In all main sewers, however, there will be accumulations of solid matter, and to provide for its decent and economical removal, catch basins are, in the best practice, built under the line of the curb-stones, at the street corners where the surface water from the gutters flows into the sewers. They have trapped connections with the sewers, and movable cast iron covers. At the junctions of the catch-basin discharges with the branch sewers, and at all changes in the alignments of sewers there are also man-holes, located in the center of the streets, and fitted with perforated covers, to facilitate inspection and the removal of deposits, also to ventilate the sewers. It is also well to place intermediate manholes, every 100 feet, to determine the location of deposits. These may be covered by the pavement, to save cost, as they need not often be uncovered.

Ventilation of Sewers.—Gas evolved by decomposing organic matter in sewers, is always dangerous to health. In small quantities it poisons the blood and produces typhoid and those other diseases commonly termed *zymotic*. In a perfectly undiluted state the gas would cause instant death. In his evidence before the Select Committee on the Sewage of Towns, Dr. R. A. Smith states that sewage is oxidised even before it leaves the town, and that poisonous gases, are evolved in large quantities. Whenever the temperature rises to about 54°, which is the usual temperature of sewers, oxidation is intensely rapid. The gases are generally as follows:

Carbonic acid	95.0
Nitrogen	2.6
Sulphuretted hydrogen	2.0
Carbonic oxide, hydrogen, and carburetted hydrogen	0.4
	100.0

The motion of the liquids constantly exposes fresh matter to the influence of the air, and the solid matter deposited in the sewers or adhering to the sides, being in an advanced state of decomposition, the exhalations are of the most deadly character.

What becomes of these gases? It has been supposed by some that the carbonic acid gas being heavier than air, finds its way to the outfall and is dissipated in the air; this is clearly an error; the law of gaseous diffusion militates against this theory. The constantly accumulating gas is soon rendered highly concentrated by the temperature in the sewers, and as soon as the pressure of this exceeds the hydrostatic pressure of the water in the traps it escapes. The bubbling noise not uncommonly heard in closets and sink traps is caused by gas escaping in this way; moreover, sewer gases are extremely soluble; water readily absorbs more than its own volume of carbonic acid gas, consequently the water in the traps rapidly become highly charged with sewer emanations, which cause it to putrefy and evolve most dangerous gases into the apartment.

The ventilation of sewers by grates opening into the streets—the delivery of these gases into the very midst of the street throngs and into the doors and windows of houses, is hardly a remedy of the evil. To disinfect sewer gases before they can reach the street, vegetable charcoal spread lightly on a perforated tray or basket has been fixed in connection with the man-holes. When dry it effectually purifies the gases, but as it absorbs water rapidly it requires to be renewed frequently. The steam and damp vapors from the sewers will in short time render it useless. Elaborate and expensive ventilating chambers have been erected on this plan in West Ham and some other places. The process is theoretically correct, but its practical value is very doubtful, for the reasons stated. It has been proposed to connect the sewers with factory or other chimneys, so that the gases may be discharged into the air at a great elevation. There is reason to believe that this method may be made successful. The expense of building special chimneys and keeping up a furnace would be too great to be entertained, unless all other reasonable schemes result in failure; but if a factory chimney exists near the summit of a sewer, a connection can be made with very little expense. A small central chimney would be useful only for a short range; the air would be drawn with great force into the sewer, through the traps in the neighborhood; while the sewers at a distance would not be affected in the slightest degree. Rain-water spouts have been used in some instances; but the objections to this system are numerous. During heavy storms, when the sewers are being rapidly filled with water and when some outlet is specially required, the spouts are required for their legitimate function; besides which, leaves and birds' nests cause frequent obstruction. The gases would, moreover, be discharged into the immediate neighborhood of bedroom-windows.

The corporation of Liverpool has recently incurred great expense in the endeavor to solve this important problem. Over 1,000 iron shafts, about eight in. in diameter, with revolving tops, have been fixed in corners or recesses. These shafts are joined to the sewers in convenient places, and are also carried far above any windows. A great reduction in the rate of mortality has followed their adoption.

Application of Sewage to Agriculture.—The following are recent facts regarding the experiments on the application of sewage to agriculture, at Paris. Two methods, which may be called the agricultural and the chemical, were to be tried simultaneously. A laboratory was also fitted up for the daily analysis of the sewage water. Near the mouth of the great sewer at Asnières, a centrifugal pump capable of raising 500 tons of liquid per day, was erected and a plot of ground, about four acres in extent, was laid out. The sewage water, merely passes along the small channels which bound the beds, in which various kinds of plants are cultivated, but especially roots; the water filters through the soil, feeds the plants and leaves in the channels a valuable deposit, which is incorporated with the soil and which applied to bare land in winter produces the same effect as good manure, and prepares the soil for spring crops. No other kind of manure is ever used at the Clichy establishment. The products are of excellent quality. From November, 1867, to July, 1868, 26,000 tons of sewage water have been applied to the soil there; the water is therefore purified naturally, and at the same time acquires a commercial value which is estimated at about one halfpenny per ton.

The report of Messrs. Bateman and Bazalgette on the sewage of Glasgow says: The application of sewage to land has not only resulted in an amazing increase of its productiveness, but, where the application is properly conducted and the ground suitable in character, the sewage is deprived of all objectionable smell and appearance, and may then be safely permitted to flow into such a river as the Clyde or into the sea on any part of the coast. Probably the most notable instance of the successful agricultural application of the sewage in this way, is over the Craigentinny meadows near Edinburgh, where the land has been made to produce 40, 50 and 60 tons of grass per acre, per annum, which is generally sold to persons, who cart and carry it away themselves, for prices generally exceeding £30 per acre, and in some instances upwards of £40. There, however, the mode of application has been defective—the ground has been overdosed with sewage, and its objectionable qualities have not, therefore, in a sanitary point of view, been wholly removed. At Croydon, the purification of the sewage of that town, by passing over grass lands in the immediate neighborhood, has been so successful that people residing close up to the sewage-irrigated land do not complain of any nuisance; and so entirely devoid of color, smell, or taste is the sewage, after having passed over the ground, that on comparing a bottle of it with a bottle of water from Loch Katrine, without knowing in which bottle the respective waters were contained, one of us actually selected the Croydon sewage water as being that which he believed was Loch Katrine water. Similar results have attended its application at Rugby, Carlisle, Barking, and other places; and there can therefore be no doubt whatever that foul sewage, after being properly and sufficiently passed over suitable land, and applied to suitable crops, may be wholly deprived of its offensive character. The land which it appears is best adapted for effecting this purification, is well drained friable clay or sandy loam, free enough to absorb the sewage and gradually allow it to filter through, but not so free or open as to allow it to pass through too quickly. Sands and gravels, too, appear to produce this disinfecting result, and all crops are apparently suited for the reception of sewage, though that to which it can be most readily applied, and which, perhaps, in its turn produces the most beneficial result in its purification of the sewage, is grass land, especially rye grass, cut green and carted from the ground.

The application of sewage to agriculture has met with two serious drawbacks in England. At first the local authorities and the farmers were at open war, and everything was carried on under compulsion. No sooner did the local boards discontinue the pollution of the natural water-courses, and apply the fecal contamination to the land, than it became necessary to endow them with power for the compulsory purchase of land needed, as no farmer would willingly permit them to use his fields for the purpose. As the prejudiced mind of the agriculturist became more enlightened by the undoubted success and value of sewage irrigation, it began to entertain another grave error, viz: that the only difference between the present and future methods of manuring land consists in the substitution of one fertilizer for another. This is a serious mistake. The one is a simple and primitive mode, capable of design and execution by any common farm laborers; the other is an accurately and carefully planned project, requiring, from first to last, a high degree of professional skill, and technical knowledge and ability. Thus it is that in the few instances where the agriculturist has been his own engineer, his attempted utilization of sewage has eventuated a miserable failure, greatly to his own surprise and chagrin, and also to the detriment of the principle which he tried to put into execution. Regarding sewage irrigation as applicable to every description of crop, it must, in every instance, necessitate some preliminary preparation, or surface formation of the land, which it is intended to irrigate. This circumstance mainly contributed to the restriction of sewage irrigation principally to grass crops, which admit of a very reckless and unscientific distribution of the fertilizing fluid. The case is otherwise where cereal crops are concerned. According to the physical contour of the land, so will the preparation of its surface be more or less expensive. As the ground must be prepared for a railway before the permanent way can be laid, so is a similar operation, in a minor degree necessary to insure the proper and remunerative disposal of sewage.

Artificial Purification of Sewage.—Various schemes for this purpose have been tried and many others are on trial and proposed. The Paris experiments before referred to, are as follows: A solution of sulphate of alumina is made in the proportions of two hundred weight of the alum to 1000 litres of water, and two litres of this solution were used for every ton of sewage to be purified. The price of the alum delivered at Clichy amounted to eleven francs per 100 kilos., about 4s. 6d. per hundredweight, making the expense of purifying a ton of sewage something less than one farthing. Lately a pure solution of the sulphate has been obtained; one pound is mixed with two or three times its own volume of water, for every ton of sewage to be purified. The solution costs about one shilling per hundredweight, and the expense of purification thus only amounts to one centime, or less than the tenth of a penny. The mode of carrying on the operation of clarification is very simple; the sewage water, after having received its dose of solution, is admitted into the basins, which it traverses slowly, while the particles in suspension are deposited as in the operation of fining; the water flowing out of the basin is so pure that it may be turned into the river. The basins are emptied about once in six weeks, and their deposit is removed without difficulty. The clarification occupies less than ten hours; the water, black on entering, becomes of a greenish tinge as soon as the solution of alum has mixed with it, and passes off at the further end of the basin pure. The manure left at the bottom dries readily when the layer is not much more than four inches thick. It passes from black to brown, cracks, and assumes much the look of cork. Very little smell is given off either from the basins or the irrigating gutters; the gaseous matters are almost immediately consumed by the air and light. The precipitated matter contains from fourteen pounds to sixteen pounds of nitrogen per ton. More than 50,000 tons sewage water have been clarified in twelve months, producing about 100 tons of precipitate. The composition and nature of this precipitate place it exactly on a footing in all respects with the refuse of mud swept from the public streets. Side by side with the practical experiments, careful scientific examinations are pursued in the laboratory. As already stated, a ton of the sewage water contains about six pounds of various foreign matters; azote, phosphoric acid, alkalies, organic and earthy matters. The precipitate contains half the azote, all the phosphoric acid, and most of the organic and earthy matters, while the clarified water holds in solution the other half of the azote, and all the alkaline matters. From these data the values of sewage water are ascertained to be as follows: A penny a ton for the fluid as it exists in the sewer collector, and the precipitate about eighteen shillings per ton; the total quantity poured into the Seine daily averages 200 tons, so that the value of the sewage water would amount to about £300,000 per annum.

The A. B. C. process of Mr. Sillar about which so much is said in the English papers, is named from the initials of its three principal ingredients, animal charcoal, blood, and clay. When this compound is suspended in water and added to the sewage, a precipitate in large flakes is immediately produced; the supernatant liquor is drawn off into a tank and a small quantity of perchloride of iron solution added. The iron compound serves to remove the sulphuretted hydrogen. It has been found convenient to add a certain proportion of alum, since the process is thereby accelerated. This process was tried at Leicester, where the lime process had previously been used. Dr. Frankland's report upon it says: The purification of sewage may be conveniently considered under two heads—1st, clarification, or the removal of suspended matters, so as to make the resulting liquid more or less clear and transparent; and 2d, removal of matters in solution. The suspended matters contained in sewage are well known to undergo rapid putrefaction and to become very offensive; consequently their removal either by filtration or chemical treatment constitutes in itself an important amelioration in sewage. But the liquid so clarified contains in solution much nitrogeneous organic matter, which is prone to become putrid even when mixed with a considerable volume of river water.

In conclusion, the results of the experiments may be thus summarized:

"1. The Sillar and lime processes remove to a great and nearly equal extent the suspended matters contained in sewage.

"2. Sillar's process increases the amount of dissolved solid impurity in sewage, but reduces the quantity of putrescible organic matter. The lime process reduces both the amount of dissolved solid impurity and the quantity of putrescible organic matter; the reduction of the last being about the same as that effected by Sillar's process, viz: rather more than one-half.

"3. To the manufacturer of solid manure from sewage, Sillar's process is greatly superior to the method of treatment by lime, although it fails to extract from the liquid more than a very small fraction of its valuable constituents."

Advantages of Irrigation over Deodorization.—The report of Dr. Frankland further concludes: "Like all chemical methods hitherto invented, both processes fail in purifying sewage to such an extent as to render it admissible into running water. It still remains a fact that no chemical process is known which even remotely approaches irrigation in its efficiency as a purifier of sewage."

The report of Messrs. Bateman and Bazalgette, before quoted, says: "All attempts at deodorization or precipitation on a large scale have hitherto so completely failed, either commercially or chemically, that, in our opinion, the idea of correcting the evil by any such process need not be regarded; and hence it becomes necessary, either to turn the sewage in its natural condition into the sea at some point sufficiently distant from populous places or districts, or, by allowing it to pass over a sufficient area of suitable lands to clear it of all objectional character, and to render it so pure that it may without fear of creating a nuisance be turned into the river or the sea." The "Engineer" in discussing this subject, concludes that every discription of disinfecting and deodorizing nostrum has been allowed a fair trial, and the practical result has been, without exception, a complete failure. They all come to grief in one of two ways, and generally in both. They all have failed to convert the solid or semi-solid residue into a marketable manure, which will sell, speaking broadly, for anything. A few of them have been successful in purifying the sewage so far that the liquid might be run into a stream, where the owners were not over particular. This is nothing more than a feat that any decently educated chemist could accomplish. The only real and efficient purifier of sewage is the soil, and no chemical process has been yet discovered which will effect this object and at the same time retain or fix the valuable fertilizing ingredients. From the recent report of the results obtained at Barking Farm, it will be perceived that there is no longer any doubt upon the subject. In spite of the poverty of the soil at Barking, the sewage has been able to confer upon it all the fecundity belonging to the richest lands. Splendid cereal crops, fields of bulbs and roots, have resulted from the application and the thoroughly efficient manner in which the farming operations are conducted.

THE SUEZ CANAL.

PRESENT STATE — PARTICULARS — USEFULNESS—ENGLISH OPINIONS.

In a communication to Paris, M. de Lesseps states that a small schooner, "La Levrette," has recently passed through the Suez Canal, and that six vessels belonging to the Egyptian fleet are about to pass from one sea to the other. It now may be safely said that this canal is opened for vessels of small tonnage; and in six months' time ships of from 2,000 to 3,000 tons burden will be able to make use of it.

The Suez Canal is about 90 miles long, and will be 328 feet wide at the water line, 74 feet at the bottom and 26 feet deep. The slopes under water are very flat—five to one. The excavation will have required the removal of 96,000,000 yards of earth. The work presents no engineering difficulty except magnitude. The cost is estimated at 60,000,000 to 75,000,000 dollars gold.

As to the usefulness of the canal, the Dutch Commission report that it will help sailing vessels bound beyond the Indian Ocean very little—ten or fifteen days in 100; but that it will save steamers fifteen to seventeen days in a voyage of 60 to 70 days. The rate of toll is not decided, and it is stated that steamers will not be allowed to use their own propellers, but will be towed by some means that will not wash the banks. The English papers are "calculating" that it will hardly pay.

An American scientific writer, sojourning in London, ten years ago, prepared an elaborate article favorable to the Suez Canal. The article was thrown out by the proprietor of the journal to which it was contributed. But, said the writer, "the project must succeed—there are no insurmountable difficulties." To which the proprietor replied to this effect, and his reply sums up the British opinion of the period: "The Suez Canal is not recognized as a proper subject for professional discussion in England. Englishmen have determined that it should not succeed." But British opinion is subject to change on this as on other subjects, and the "Practical Mechanic's Journal" now makes this handsome acknowledgement.

The Suez Canal—after years of labor and perseverance againt every obstacle and discouragement, enough alone to immortalize the names of Lesseps and those who have, like his able contractors Lavalle and Borell, stood staunchly by him through every difficulty—at last begins to prove itself to the world at large, and even to the most incredulous eye, as about at an early period to be accomplished. In fact, in some sense, it is so already. The Sweet Water Canal has already conferred great agricultural benefits upon the country through which it passes, and must prove hereafter a source of uncountable riches to Egypt, and of great revenue to the canal company. The English engineer who showed himself, as regards this Suez Canal question, the only competent one —for Mr. John Hawkshaw, in his able report, boldly stated that it was not only practicable but easy to construct, and that the dogmata of Robert Stephenson as to the impossibility of keeping it open were purely chimerical—has stated, that he would undertake to irrigate the whole land of Egypt, *i. e.*, all its tillable land, from that canal.

A condition produced by the relations of the salt water or great ship canal and the arid climate of Egypt, which Stephenson never thought of, has since been carefully taken into account, and it is now certain that whenever the sea shall be let into and fill the Bitter Lakes, the evaporation from the water surface alone will be such as to cause a considerable current through the canal, which, according to Stephenson, would be "no more than a stagnant ditch;" indeed, the question has been raised whether the scour due to this cause and to alternate action of the tides, though these are small at either end, may not prove more than desirable. The effect, however, of this evaporation will unquestionably be to totally and rapidly change the whole climate of Egypt, so that, irrespective of any irrigation, it will probably become sufficiently moist to gradually put an end to the Egyptian Sahara, through the unseen working of the forces of nature. Should this even in a minor degree be realized, and there can be little doubt upon the subject, it will be probably the most wonderful result in the modifying of cosmical forces as found in nature ever achieved by human means.

England has all along occupied a most unenviable and unfortunate position as regards this grand project, of which France may be so justly proud, and the completion of which we hope the Emperor may live to see, and to know that it will be one of the events by which history will mark his reign. But we will not go back upon the unpleasant track of misjudged policy, mainly due to Lord Palmerston's political prejudices as to Eastern affairs, sustained by R. Stephenson's engineering misjudgment, in which the facts and deductions were fitted for the political foregone conclusion, rather than to nature and reality. The recent tardy sort of half retraction of ancient opposition and prejudice on the part of the *Times*, and some other English leaders of opinion, is but a pitiful display of grudgingly admitted error and half-given praise. The old story, "it will never pay," however, is still raised, but no attempt is made upon any solid and sensible basis of figures, in Great Britain at least, to prove that that is so.

RAILWAY ACCIDENTS.

HASTY CONSTRUCTION—IMPERFECT EARTHWORKS.

The "Railway News" divides railway accidents into two classes; those arising from moral causes, such as disobedience of orders, and those arising from physical causes, such as mal-construction. Particular reference is made to the settling of embankments. A few inches above section line are generally allowed, but it is never enough; embankments have been known to shrink a foot to the yard—that is to say, an embankment of thirty feet high, left full height, has been known, after excessive rain, to sink ten feet and some even more than this—sand-banks not so much. Here, then, is the primary cause of numerous railway accidents. The construction of railways is always hurried forward; cuttings and embankments are often begun and finished before any wet has been on them; they are prettily carried out and completed according to the plans and sections, the sides are nicely soiled and sown, and the young engineer, having his exact depth of cutting, exact height of embankment, and exact two feet of ballast, all according to specification, is satisfied. In nine times out of ten the practical navvy knows this is wrong; but it matters not to him. He must obey the engineer, and he gets paid; and in the contingency mentioned he may possibly get paid a second time for the same work. Banks should be—and are supposed to be—constructed of half round form, the centre six inches higher at least than the sides, in order that, when the water makes its way through the ballast, it may meet this convex formation, and so be sent both sides out over the embankments—good in principle and effectually preserving banks in good order when thoroughly carried out; for it is not the quality of rain that falls that spoils banks and renders them dangerous, but the quantity that finds its way into their centers. But on the contrary, when the rain comes the banks go. The ballast is now on; they cannot be opened out and remade, because of the traffic and for other reasons; so more ballast is heaped on, as many feet of it in many instances as there should be inches, the consequence being that the symmetry of the bank is lost, the rotundity between ballast and formation is gone, the water settles into the embankment, and ballast for the future does more harm than good, the water finding its way out by means of slips and other channels that strain the permanent way. The sleepers may be sound, the rails good, and the fastenings of the most approved kind; but if this strain, unprovided for in office books, comes on, away goes the road, and under some extra speed or weight, or during the 48 hours between Saturday and Monday that the platelayer's watchful eye is off his beat, the fastenings are unfairly tried, the guage is forced out, and off goes the train.

This was, no doubt, the case at Tuxford, on the Great Northern, some five or six years ago. About two years ago it was the cause of that terrible accident on a heavy bank on the Chatham and Dover, and more recently, on the branch line between Leamington and Rugby, this was evidently the real cause of the accident. Of course accidents occur on banks and in cuttings too from other causes, and it is not denied that sharp curves and steep gradients do their part; but the above is chiefly the cause of the class of accidents we are now discussing, and they are only to be avoided by the non-ballasting of embankments until they have had two or three seasons on them, and have had time to become permanently consolidated. If lines must be opened before that occurs, less risk a thousand times to run (at reduced speed, if you like) over banks without any ballast at all. By good management and constant packing, the road can be maintained almost as well without, as with ballast; indeed, very much better than on banks where the super-quantity of ballast acts only as a perfect trap to catch and hold all the rain that falls; and then, after two or three winters have been on the banks, the road may be finally lifted, set, and ballasted, and it will never cause either trouble, uneasiness or accident.

PROGRESS OF ELECTRO-METALLURGY.

COATING SHIPS' BOTTOMS—SILVER PLATING, ETC.

From the "Mechanics' Magazine."

In the year that is just ended, but little has been added to our knowledge of the laws of the electro-deposition of metals, and not a great deal to the application of laws already known; still, some progress has been made, in the modes of carrying out these arts. Last year we noticed a new application of electro-coppering, as applied to the coating of ships for the prevention of fouling and corrosion, which had then but newly been tried, and we were then in hopes that by its means copper would soon be successfully applied to the bottoms of ships for their protection, but yet little progress has been made in that direction. Not that a firmly-adhering coating of copper cannot be applied to iron; we have seen this done repeatedly, but the difficulty is in applying it to ships. It can be done to ships' plates before being built into the ship; but the rivets must be coppered also—yet, if coppered, how are they to be riveted? Even if copper rivets were admissible on the score of cost and strength, they could not be on the score of electric action. For if they contained lead, as almost all commerical copper does, they would become electro-negative to the electro-plastic copper, and so assist to destroy the coating of the plates. It is true that electro-plastic copper could be made into rivets, but this would be at double the cost at least, and this would enhance the price enormously, the rivets required being both very large and numerous. But besides these considerations, copper rivets would not be strong enough. Are we, then, to give up all hope of coating iron ships with copper? By no means; but it will not be by the direct application of the copper to the iron. We think the difficulties of such a process are too great to be successfully overcome. The process which appears to us most likely to succeed, is to coat the plates of iron with copper by electrolysis (the iron giving strength), and with these plates to sheath the bottom of the ship, between the the sheathing and the ship an insulating substance being interposed. Of course, in this way, a ship could be sheathed with ordinary commercial copper, but the sheets would have to be of sufficient thickness to prevent buckling and bulging from the insulating material, so that with plates wholly of copper the sheathing would be six or eight times the cost of that we have hinted at. We should like to see thin iron plates coated with copper, applied as sheathing on a large scale. We have seen it tried on a small one, and have but little doubt of its success on the large.

In electro-coating with silver, as applied to copper, brass and German silver, there is nothing new; except with regard to the coating of the alloy of lead and tin (common soft solder) with silver. This practice has become much more extended, and is a deception and a cheat. The forks and spoons are roughly made of a common kind of German silver, or, rather, a highly speltered brass, without a particle of nickel in it, and then coated with common solder by immersion in the melted metal; they are then easily rubbed down smooth, and the expense of filing, burnishing and polishing saved, and this is the reason why this practice has been resorted to. There certainly is more difficulty to the ordinary practitioner in coating this alloy with silver than in coating German silver, brass or copper. The same method cannot be pursued with this alloy as with the above metals. Mercurial cyanide or nitrate is of no avail to prepare it for the silver; instead of this as a preparation, the spoons or forks are suspended in a boiling solution of caustic potash or soda for a short time, and then transferred quickly to the silver cyanide solution, to which is attached a strong battery, so that they may be quickly coated with silver, and the action of the cyanide solution on the alloy is prevented by rendering it strongly negative. When they are coated they look as well as other spoons and forks, but they soon chip, owing to the softness of the alloy under the silver, as well as the imperfect adhesion of the silver to the alloy.

There is another branch of electro-coating, wherein some progress has been made during the past year, that is the coating of iron, steel, and cast iron with copper and silver. To make silver to adhere firmly to iron and steel has been a desideratum much sought after for many years; indeed, ever since electro-plating was discovered. It has always been found much less difficult to make copper adhere to iron than to make silver adhere to it; consequently, it has hitherto been the practice to coat common dessert knives and nut-cracks with a thin coat of copper and then with a coating of silver. But these are much inferior to the solder-plated knives, called close plated, which is a thin sheet of silver soldered on to the blade with common solder. These are called the best plated knives, though plated with soft solder, because hard or silver solder is not applicable to plating knife blades, on account of the heat necessary, but to carriage, harness and coach fittings, hard solder plating is applicable, but its expense prevents it being much used. This new process referred to above is equal to hard solder plating, but cheaper than soft solder plating. The inventor of it calls it pyro-plating, because the fixing of the silver is done by heat, as also the preparation of the articles for silvering. Some four years ago, a patent taken by Mr. J. Baynes Thompson describes a process for obtaining a pure surface, whereon to deposit the silver, viz: by depositing a film of iron on the article. But within the last six months the same gentleman has taken out another patent and abandoned the previous one. In this new process there is no intermediate coating of any other metal, the silver being deposited direct on the iron or steel. The surface of the iron is purified by nascent hydrogen, the hydrogen being produced by the electrolysis of hydrate of potash or soda; the inventor prefers hydrate of soda. With care, no other salt need be added to this solution, but in manufacture such care can hardly be expected; therefore, it is expedient to add a small quantity of one of the compound cyanides: those preferred are the nickelo or cobalti-cyanides of potass. The necessity for these salts is this: If care be not taken to regulate the current of electricity according to the strength of the solution and the number of articles in it, as well as the heat of the solution, sodium will be deposited on the articles as well as hydrogen, and if transferred to the silver solution with that on, the silver will not adhere. The compound cyanide prevents that.

When the article is coated with silver it is subjected to a heat of between 400 deg. and 500 deg. Fah., so as to fix the silver, and after that it will stand a red heat without injuring the coating. Knife blades and all cutting instruments are silvered at a pale straw temper, so that the burning in or fixing of the silver may bring them down just to a proper cutting temper. We understand that the inventor has been fitting up a manufactory for the production of silvered articles in iron and steel, and that it will very soon be brought into full operation. Beyond these, nothing further of note has been done in electro-metallurgy; and though the advance during the last year has not been very striking, still gradual progress has been made.

SINKING MASONRY IN MARINE MUD.—Contracts will shortly be issued for the construction of a floating basin at Bordeaux. Preliminary surveys and trials have been made, the result of which is that the difficulties of construction turn out to be less formidable than was imagined; the works will have to be carried out on a bed of marine mud about twelve yards in depth, but which is easily traversed by blocks of masonry fourteen yards high and with a surface of about six yards. Three wells have been made by means of blocks formed at the level of the ground, and which descend by their own weight as fast as the soil is taken out from the well. This operation presents, it is said, no real difficulty when the mud is dense enough to prevent the water rising in the well, and if a stream should flow in, a pump capable of lifting about 300 gallons a minute would soon pump the well dry. Under the conditions above mentioned the masonry descends to the depth of thirteen yards, exclusive of a stratum of very pure sand, four feet or five feet thick, which lies beneath the mud. Masonry thus placed has the solidity of a rock.—*The Engineer.*

RESISTANCE AND TRANSMISSION OF MOTION.

By Prof. Henry Morton, Ph. D. From the Journal of the Franklin Institute.

There are a number of phenomena more or less directly connected with the effect of high velocity in overcoming resistances, which are commonly regarded as forming a class by themselves, and requiring a special hypothesis for their explanation, or if treated in the established method, calling for an exercise of faith in a train of reasoning not in itself quite unexceptionable, which is at the least a sort of discomfort to ordinary minds. As an illustration of the phenomena to which we allude, we may cite the oft-quoted experiment of shooting a tallow candle through a pine board, the piercing a slate with a pistol ball, without cracking it, &c.

In an able paper by John C. Trautwine, C. E., entitled "Remarks on Force, Motion, and Inertia," published in the "Journal of the Franklin Institute," Vol. XLIV., p. 197, some of these difficult questions are very fully expressed. We will quote, for want of space, but one of the illustrations used, although we would strongly recommend the article to all interested, as an accurate and entertaining discussion of a subject which has been inadequately treated by some even of the highest authorities. After various other and more elaborate illustrations, Mr. Trautwine says: "The ordinary coupling between a locomotive and a heavy train, would break, under the action of an engine capable of imparting to the train at one impulse, a velocity of forty miles an hour; yet it safely transmits the same amount of moving force when imparted by a succession of milder impulses," and further on, "it would seem, that *moving force will of itself* sever mediums through which we may attempt to *transmit* too much of it, to *unresisting matter*, as well as to resisting force."

We believe that the obscurity of this subject will be greatly relieved, if only a little thought is given to the nature of those molecular forces which are the most usual active agents in the resistance and the transmission of motion. It will then be seen that these are forces which differ in nothing but their range of action, and intensity, from gravity, or other like energies, and may be fairly compared with them in their mode of action.

There is however, another point, which, though self-evident, is apt to be overlooked in our study of all forces, and that is their relation to time, in the respect, that the effect of any force must be proportional to its time of action. Thus, if a force is capable of producing a certain effect in one instant, it will do the same twice over in two instants, and can do but half as much as this in half the time. We should then first regard the particles of bodies as maintained in their relative positions, not by any general and indefinite condition of contact, but by the constant action of certain forces of great but limited power, and exerting this power, not without reference to time, but on the contrary, with entire dependence upon it; so that each element is exerting so much force in so much time, more in more time, less in less time, in a direct proportion.

These general principles being premised, we will presently assume a case involving the transmission of motion, and test our theory in its explanation. Our conception of this subject will be rendered more easy, however, if we first consider a parallel case in which gravity might take the place of the transmitting or molecular force. Imagine the earth at rest in space, with a heavy body in contact with it at some point. If, now, the earth received a motion in a direction radial to the point of contact and away from it, the heavy body would remain in contact so long as this motion was not greater than that of a body falling from a state of rest, *i. e.* (sixteen feet in the first second, and so on). In other words, the attractive force between the heavy body and the earth (which here represents the molecular force of our actual experiment), is just equal to that which we express by so much matter (the weight of the heavy body), moved sixteen feet from a state of rest; this power being put forth in the time of one second. If, now, we required a greater force to be transmitted by this attraction of gravity; either by asking it to move a greater mass at the same rate (as by connecting the heavy body by a string, with another so placed as to be free from all resistances to motion), or by demanding a higher velocity (as by supposing the earth to move more than sixteen feet in the first second), we should simply rupture the connection between the earth and heavy body. By keeping within the limits of the *transmitting* force (which in the above case was gravity, but might be any other), we can transfer, part by part, any amount of force to the second body, which will be converted into motion in it, and be so stored up and accumulated without loss, all resistances being removed.

We will now take up an actual case of transmission to which our principle should supply an explanation. A weight, W, rests without friction on a level plane, and a power, P (derived say from the action of gravity upon a heavy body), is caused to act upon it by means of a cord passing over a fixed pulley. In an instant of time, gravity exerts a certain pull upon the heavy body, which we may assume to be transmitted instantly to the first point of the cord; but how is it to travel along the cord? It is clear that the only mechanical connection between the successive points of the cord, is their *cohesive attraction for each other;* it is then by what we may be allowed to call a *stretching* of this attractive force, that the power, P, can be transferred along the cord to W, and by no other means. Now, this molecular force is, as we have already seen, properly expressed by, and in fact constituted of, so much power in so much time. If, then, we draw one of these atoms from another with a force which is greater in the *same time* than that uniting them, a rupture will occur, and so much force only be transmitted as was exerted by the molecular power during the time that the weight was acting upon it.

The questions and conditions here noticed, lead us to another cognate subject of similar difficulty, and amenable to similar treatment; we allude to the relations between the moving force and the work done by a moving body. We say and know that the *vis viva* or work done by a moving body, varies with the square of its velocity, while we know, by our previous reasoning, that the force expended in giving it that velocity, only varies with the velocity itself. Thus the force of gravity will give a falling body a double velocity in a double time, during which it must have exerted a double force upon it. Here, then, we have a double force, doing a quadruple work. Is this because, by some wonderful and recondite property inherent in "velocity," the double power has been indued with an again doubled efficiency? Many writers leave us to think so; but we, on the contrary, believe that the work done *only seems to increase* more rapidly than the power implied in the increased velocity, by reason of a *loss of efficiency* in the resistances, in the overcoming of which the "work" consists, and in fact, that work in this sense, is no true measure of force.

As we have before seen, the molecular forces (which are those that most commonly play the part of resistances) as well as all others, exert powers proportional to the times of their action. If, then, a moving body with a certain velocity, overcomes a certain number of these resistances, or, for example, penetrates a medium to a certain depth, before its motion is arrested, it has overcome so many resistances, each acting for such a length of time. If, now, the same body with a double velocity, meets the same medium, it will penetrate each resisting element in half the time, and so receive from it but half the resistance it experienced before. If, then, its total force were *only equal* to what it was at first, it would go twice as far, or overcome twice as many resistances; because each of them would be but half as effective as at first. But as we know the double velocity implies a double total force, and thus, considering the doubling of the force and the halving of the resistances, we see why the number of these overcome, or the work done, should be fourfold. Similar reasoning would apply to the case of a body resisted in its upward motion by the force of gravity. A double velocity would give a four-fold height to its upward path, because, traversing each distance in half the time, gravity would exert but half its former effect within the same space, and so on, as before followed out. The body would come to rest when exposed *for a double time* to the resisting force of gravity.

It may be objected that the time of action is not the true measure of a force, but rather the distance which it causes a body to move in a given time. But that this is not so, will be seen when we consider that any velocity once implanted in a body, needs no force to maintain it, so that all the motion afterwards executed by reason of that element, is a clear gain having no equivalent of expended force as its representative. Thus, a falling body acquires during the first second, a final velocity of thirty-two feet per second. If gravity then ceased to exist, it would still travel this distance in the next second, while if the force still exist, and is to be expressed by the motion produced, we would have it responsible in the first second for sixteen feet, and in the next for forty-eight. It is precisely this which introduces the philosophical error into the method of estimating force by the product of mass, into the square of the velocity.

But again, it may be said, the true measure of a force is the heat it develops, and this, as we know, varies with the square of the velocity. We would reply that all development of heat is unquestionably of the nature of overcome resistances. Thus the vibratory motions given to the atoms of bodies, are given in opposition to and by overcoming their molecular forces, and therefore, as in other cases, these forces will each individually oppose a *shorter* resistance to a body with high velocity, and thus render a greater number of their companions necessary to counteract its motion. In other words, the previous explanation may be applied word for word to this case. Or, we may say, the change produced in the individual atoms of a resisting medium, which we have heretofore called overcoming of their resistances, *is* heat. Therefore, if a double velocity overcomes a four-fold number of resistances, it develops a four-fold amount of heat.

In conclusion, we would again remark that the foregoing discussion is in nowise intended as suggesting a new system of mechanics. The rules at present employed are perfectly correct in their working, and more convenient in form, we think, than any which could be established on another basis. Like many rules and methods in mathematics, they are without reference to the rationale of the process, but accurately fitted to its requirements. Thus, for example, to take a simple case in arithmetic, in place of dividing one fraction by another, we invert the second and multiply. This is perfectly correct and unobjectionable as a method of obtaining certain results, but if the final expression (e. g. $\frac{1}{2} \times \frac{3}{1}$) were regarded as a rational explanation of some process (the inverting step being ignored), it could not well convey a very true or satisfactory impression. So when we calculate the efficiency of various forces by the formula $f = mv^2$, we are simply transferring one v from the denominator of a fraction expressing the resistance, to the numerator of the quantity expressing the force, which we have a perfect right to do, provided that we recognize this as a *mathematical process*, and not as the expression of a *physical fact*. Our object in writing the above, is to make clear that this *is* the actual state of the case, and thus, in this and the other points noticed, to offer to those who may feel the appetite for such a supply, the reasoning which has satisfied in ourselves the craving after a rational account of things that had a certain air of paradox about them, as commonly enunciated.

THE DRYING PROPERTIES OF VARIOUS PAINTS.

From a Paper by Charles Tomlinson, F. R. S., read at the Society of Arts, Dec. 9th.

The question we have to consider is "Why does paint dry?"

VOLATILE LIQUIDS.—When we boil water a process of evaporation goes on, and the evaporation is not superficial merely, but from every part of the liquid. Again, if we apply heat to oil of turpentine contained in a retort, it will boil a little over 300 deg. Fahr., and the vapor may be collected and condensed in a cooled receiver; but if we try to boil linseed oil, for example, it will not only not distil over, but it will blacken and decompose instead of boil. If we moderate the heat so as not to carbonize it, then it will lose about one-sixth of its weight and become thick, tenacious, and viscid; forming what is called printer's varnish. Raise the temperature above 600 deg., and if air be present the oil will take fire and burn quietly without further external heating, until nothing but tar or charcoal is left. If, however, the burning be interrupted by closing the vessel, a brown viscid substance will be left, known as birdlime.

Turpentine belongs to a class of oils known as *volatile;* that is, they can be raised into vapour by means of heat, and under certain conditions will evaporate or dry up. Linseed oil, on the other hand, which cannot be distilled, belongs to a class of oils called *fixed.*

FIXED OILS, PAINTS.—House paint, omitting the coloring matters or stainers, consists of three ingredients: 1st, white lead or white zinc; 2d, a fixed oil, such as linseed or nut, used for the purpose of reducing the white to a soft paste, to which is afterwards added variable proportions of linseed or other oil for thinning the paint; 3d, the dryer. Dryers consist of litharge, oxide of manganese, and sugar of lead. Linseed oil is heated with about one-twentieth of its weight of litharge, which the oil completely dissolves, and is then used as a dryer. A similar heating with manganese or sugar of lead also improves the so-called drying properties of the oil.

OXIDIZING OIL—EXPERIMENT.—But what would be the effect of omitting the dryers altogether in the composition of the paint? I have no doubt most painters would say that the paint would never dry. Let us see the result of a careful experiment performed by Chevreul some years ago. Four oak strips were painted, each on one side, with a paint composed of white lead and linseed oil, and the other side with a paint composed of white zinc and linseed oil. The dryer was omitted in all cases. The strip No. one was exposed to the air to dry; No. two was put into a bottle of the capacity of 3.52 pints and closed; No. three was put into a similar bottle, containing dry oxygen gas; No. four was put into a similar bottle, containing dry carbonic acid gas. After 24 hours, No. one lead paint was almost dry; the zinc paint had set, but was not dry. No. two lead paint was almost dry; the zinc paint had set, but was not dry. No. three lead and zinc paints were perfectly dry. No. four paints were still wet and fresh, and had undergone no change. After seventy-four hours, Nos. one and two paints were perfectly dry. No. four lead paint had almost set, but it had no adhesion to the wood, and could be easily removed by friction; the zinc paint had undergone no change, but stuck to the finger like fresh paint. In another experiment it was shown that in drying in a confined volume of atmospheric air, the paint had absorbed all the oxygen, and left nothing but pure nitrogen in the bottle.

Paint dries, not because it loses anything, as in the case of ordinary drying by evaporation, but because it absorbs oxygen from the air, and solidifies in combining with it. The drying of paint, is not, therefore, a mechanical effect, as in the case of evaporation, but a chemical one, in which there is a change of properties attending a change of state from liquid or viscid to solid. Linseed oil exposed to the air in thin layers dries up into the form of a resinous, transparent, moderately elastic mass resembling caoutchouc. This property of absorbing oxygen and gradually becoming solid, also applies to walnut, hemp, poppy, grapeseed, safflower, and some other oils, and hence such oils are termed drying oils. In undergoing this change these oils undergo slow combustion, and give off carbonic acid. Under certain conditions the drying oils absorb oxygen so quickly as to take fire, as when the cotton-wool, tow, &c., used in cleaning machinery is thrown aside, and has thus led to conflagrations.

According to Mulder, the difference between non-drying and drying oils arises from the presence of oleic acid in the latter. He compares drying oils to blood; they absorb oxygen and give off carbonic anhydride. To prove this in the case of linseed oil, fragments of pumice stone were ignited, left to cool, and then put into a bottle, and the pumice was moistened with boiled linseed oil, the effect of boiling being to raise the oil into a state of greater activity. Air previously deprived of carbonic anhydride, was next passed over the pumice, and then into a vessel containing baryta water, which, in a few minutes became turbid from the presence of carbonic acid, due to the slow combustion of the oil. Roughly speaking, the setting of paint is due to the absorption of oxygen; hence we can understand why the painters, in order to prevent their brushes from getting hard, put them into water when they leave off work; and also cover a painted surface with water when they want to keep the paint from setting.

NON-DRYING OILS AND PAINTS.—The oils that do not absorb oxygen, are rape, colza, olive, almond, and many animal oils. By exposure to air they become gradually changed, but in a different manner as compared with drying oils. They become rancid from the fermentation of the cellular substance of the plant or animal from which the oil was obtained. They lose their color, and, to a certain extent their fluidity, and acquire an acrid, disagreeable taste. Such oils are, of course, quite unfit for the purposes of the painter, although there is ground for suspicion that linseed oil is sometimes adulterated with a cheap fish oil, the result of which in the paint is to produce a disagreeable kind of stickiness which is all but permanent.

Besides white lead, or white zinc, as the basis of paint, white antimony has also been proposed. In order to determine the relative merits of the three, M. Chevreul instituted an experiment in which ten grammes (154 grains) of pure linseed oil were mixed up with sufficient quantities of the three solids without the addition of any dryer. It was found that the zinc paint covered a less surface than the lead, but more than the antimony paint. The drying of the different coats of the three paints required very different times, as will be seen in the following table:—

Coats.	Lead Paint. Days.	Zinc Paint. Days.	Antimony Paint. Days.
First	4	18	50
Second	$3\frac{1}{2}$	15	28
Third	3	5	27
Total	$10\frac{1}{2}$	38	105

Hence it appears that lead paint dries much more quickly than zinc or antimony paint. Indeed, unless it were possible to hasten the drying of zinc paint by the addition of a dryer, it would be of very little use in industry, since the practice of house painting requires that not more than two or three days shall elapse betwen the application of the first coat and that of the second.

Antimony paint is also too slow in drying to be used. A tin paint was also tried, but the oxide of tin was found to delay the drying of the oil. Pure linseed oil dries more quickly on glass than when mixed with oxide of antimony, so that this oxide is actually anti-siccitive relatively to glass.

Dryers.—We now come to the dryers, such as litharge, manganese, etc., and their action is very remarkable in causing the paint to absorb oxygen quickly and decidedly For example—two cubic centimetres of linseed oil absorbed, in thirty days, 2.445c.c. of oxygen; but the same quantity of manganese dryer absorbed 21.45c.c. of oxygen; while a mixture of the two, consisting of 1.56c.c. of linseed and 0.44 of the dryer, absorbed 30.826c.c. of oxygen. That is, the absorptive, or, as a painter would say, the *drying* power of the mixture is far greater than the sum of the powers of the two oils, since 1.56c.c. of linseed oil absorbs of itself 1.985c.c. of oxygen, and 0.44 of the manganese dryer 4.749c.c. of oxygen in thirty days, the sum of the two absorptions being 6.714c.c. But the mixture really absorbed 30.826c.c., or more than four and a half times as much as the same fluids absorbed when exposed separately.

Experiments, scientifically conducted, have also shown, that, in preparing his dryers, the painter wastes both good materials, fuel and time. He boils his oil too long, and maintains the temperature too high. The usual mode of preparing dryers is to heat the linseed oil in an iron pot until it appears to boil. The surface is skimmed from time to time, and after from three to six hours, about one-tenth, by weight, of litharge is added, and the heat is maintained five or six hours longer; or 100 parts of very old linseed oil is heated about six hours, when six parts of litharge and about three of burnt umber are added. The heat is continued six hours longer, when the liquid, after being left quietly to cool, is decanted. For the manganese dryer, the oil is heated at the so-called boiling point during five hours; peroxide of manganese is thrown in, and the boiling continued for eight hours. We have already seen that the boiling is not the formation of vapor, but the escape of gas-bubbles due to decomposition.

Chevreul's experiments prove that pure linseed oil is more siccative after three hours' boiling than if not boiled at all; but is less siccative after five hours' boiling than after three. The oil boiled during three hours with one-tenth of litharge is much more siccative than if heated without the addition of this oxide; so that the drying property is not conferred on the oil by the action of heat, as some have supposed, but it is by the mutual action of the oxide and of the oil, assisted by a high temperature, that the drying properties are developed. Litharge is more siccative than manganese; and what is very curious is, that litharge, heated once with oil, is more active than fresh litharge. It is still more curious, that manganese that has been heated several times with the oil is more active than fresh manganese. But this excess of activity in the oxides is no longer exerted on oil that has already been boiled five hours. All the experiments proved that the drying property of linseed was injured by a prolonged heating at high temperatures; and the remarkable and unexpected result came out, that linseed, exposed to the temperature of from 100° to 176° Fah. during six hours in contact with ten per cent of manganese, can be used immediately in painting without the addition of any other dryer. Linseed oil alone, exposed to a similar moderate temperature, improves in its siccative property, but not sufficiently so to dispense with the manganese. A very energetic dryer is obtained by boiling the oil for three hours only in contact with fifteen per cent of the metallic oxide.

This completes the first branch of Mr. Tomlinson's paper. In the following number we propose to continue the subject of paints, especially the drying of paints on metals, various woods and other substances, and the influence of turpentine and other ingredients.

RECENT RAILWAY WORKS AND PROJECTS.

Compiled from "Engineering," "The Practical Mechanic's Journal" and "The Engineer."

The great railway work of the year has undoubtedly been that across the plains and mountains of Western America—the Pacific Railway. The particulars of this work have been so often given that we need only say here that will form an unbroken line of railway communication across the continent from New York to the waters of the Pacific—a distance of over 3,000 miles, of which a few hundred miles only, await completion. It possesses, however, but little engineering interest beyond the fact that it crosses the two highest summits yet attained by railways, the summit in the Rocky Mountains being 8,242 feet, and that in the Sierra Nevadas 7,042 feet above the level of the sea, the mountains themselves rising considerably higher. These great elevations are, however, approached from such long distances, except on the Pacific slope, that there is nothing exceptional in the gradients or curves, nor are there any heavy tunnels or earthworks, nor important bridges. Indeed the "track laying" has gone on at the rate of three miles or more daily in each direction, and the line is expected to be open throughout in July next.

The most interesting line opened during the year is the temporary railway over Mont Cenis, overcoming a summit level 6,870 feet above the sea. On the Italian side the gradient for some considerable distance is one in twelve, while for a good deal of the distance on both the French and Italian slopes the inclination is at nearly the same rate. Upon all the inclines steeper than 1 in 40, in the whole line of 48 miles, a middle rail is laid in the very narrow gauge of 3 ft. 7½ in., and additional adhesion is obtained by means of horizontal gripping wheels, worked by the engine, and pressed with a force of from 5 to 15 tons against this mid rail. There are curves of two chains radius connecting the zigzags by which the line ascends the mountain. Of the working of the line and its prospects we have spoken elsewhere.

The Mont Cenis tunnel, and its progress we have recently described. The promised success of this undertaking has led M. Flachat, president of the society of Civil Engineers of France, to propose other lines across the Alps. After pointing out the daring rapidity with which all the rest of Europe has been furrowed by lines of railway, and showing that the territory of the Swiss Confederation is far behind the rest of the Continent in this respect as in others, he states that three great railway lines ought to be opened across the Alps, viz: by the Lukmanier, the St. Gothard, and the Simplon passes. While France is most interested in that of the Simplon, Germany is most so in Lukmanier. Switzerland is hostile to any line over the Simplon, because of its jealousy of France. Italy hails with pleasure any or all of them, having no choice except for whatever line shall enrich her most. M. Flachat after reviewing the success of the Mont Cenis tunneling, which is now about 1.9 meteres per day for each face of heading, and the probable improvements in tunneling machinery, concludes that tunneling in the Alps, upon a scale such as these and like vast ranges of mountains demand, is a matter of certainty now as to success, economy, and amount of cost, and that hence huge tunnels ought no longer to oppose the progress of the engineer in opening out such mountain barriers.

The particulars of the various tunnels proposed, compared with the Mont Cenis, are as follows:

Name of Tunnel.	Length. Metres.	Summit above sea. Metres.	Cost. Francs.
Mont Cenis.....	12,220	1,200	61,100,000
Simplon.	12,080	1,300	60,000,000
St. Gothard....	15,480	1,110	78,000,000
Lukmanier.....	1,710	1,750	30,000,000

Without going through his figures, which are probably far from conjectural—for it is to remembered that the St. Gothard line, at least, was surveyed and laid out in detail some years ago—he arrives at the conclusion that the total cost of establishing the three great linos of passage, and placing them in full communication with the railway systems of the countries to the north and south of the Alps, would reach a total cost of 387,800,000 francs, or some $78,000,000.

Largo railway undertakings are going forward in Russia, Hungary and Roumania; but in India and tho colonies railways have made but slow progress. No active steps have been taking towards the construction of the Intercolonial Railway through New Brunswick, although the large loan for making it was guaranteed by Parliament a good number of months ago, and half the loan has been taken up.

A railway has been at last begun across the Isthmus of Honduras, between the Atlantic and Pacific oceans. The length is to be 231 miles, overcoming a summit of 2,956 feet. The cost is set down at £8,000 per mile, but enough is known of the almost impenetrable forest and the unhealthy climate of Honduras to convince us that a far larger sum than this will be necessary.

An agitation, without any substantial results, was commenced, some months ago in Canada in favor of 3 feet 6 in. gauge railways. The whole scheme appears to have dropped through, and singularly, no particulars of the working and financial results of the same gauge on the Queensland railways have been furnished by the parties who have promoted other lines of the same gauge. A railway across Canada is proposed, which, if carried out, will absorb a capital of some $20,0000,000.

In Turkey there is a fine field for the construction of railways, and one scarcely inferior in China. *

As to French railways, there is an impression that it is because Government so limits them in extent that they all pay well, and that they are too few to accomodate the people. The list under survey or construction at the beginning of the year would seem to show that this want, if it exists, is being rapidly supplied. Among the principal new lines, are the following: Paris to Dieppe direct; Orleans to the sea by Honfleur, Lisseux, &c., 165 miles; Soissons by Buire, Vervens, Lugny, &c., to the Belgian frontier; Auch to Toulouse; Cercy-la-Tour to Grilly-sur-Loire; Cambray to Gannes; Niort to Cholet, 80 miles; Bergerac to Libourne; Méru to Beauvais; Flers to Condesur-Norreau; Avallon to Dracy-Saint-Loup; Aix to Marseilles; Epernay to Romilly; Napoleon-Vendeé to La Rochelle; Yevot to Dieppe; Havre to Lille; Bordeaux to Pauillac, and various branches of the Orleans and Rouen, and the Northern railways, and a line connecting the Eastern Railway of France with that of theDuchy of Baden, between Saint Louis and Leopold's Lake.

In Great Britain although the past year has not been marked by active railway enterprise, several important undertakings have been completed or carried forward. In and near London the principal works have been the Midland Extension, now open through to Bedford and the north; the Metropolitan and St. John's-wood, opened to the Swiss Cottage; the Metropolitan Extension, now completed to Westminster, and the new line of the South-Eastern, *via* Chiselhurst and Sevenoaks. The Midland Extension, with its four lines of rails and its great station at St. Pancras, is now one of the most important of all the railways out of London, and it may be expected not only to cheapen the transport of coal from Derbyshire, but almost literally to build up a new series of suburban towns extending even beyond St. Alban's. The St. Pancras station has been so often described, that it need only be noted that its magnificent iron roof has a clear span of 240 feet, the widest yet attempted, and that it forms altogether the finest example of railway architecture in the kingdom. The Metropolitan and St. John's-wood presents no striking features as an underground line, the ascent of one in 27 to Hampstead not having been begun. When completed, the line is to be 2¾ miles long and is to rise 235 feet above the level at Baker-street, three-fourths of a mile being inclined one in 27, with a station half way up. The Metropolitan Extension, has some very interesting work. The Metropolitan District Railway, under the Thames Embankment, has made but little progress as yet; nor is the East London, to be carried through the Thames Tunnel, far advanced. The new line of the South-Eastern, *via* Sevenoaks, is noteworthy for a considerable amount of tunneling, and for heavy earthworks, and also for some especially fine brickwork in its bridges. The London and Brighton Company have opened a new line between Brighton and Tunbridge, saving fifteen miles in distance. The London and North-Western Company's new line, *via* Runcorn, to Liverpool, was to have been opened at the end of the year, this line, as our readers are aware, crossing the Mersey on a long bridge, of which the principal portion consists of three pairs of lattice girders, each of 300 feet span. The Caledonian Company have made a new line over which trains are run between Edinburgh and Glasgow, without the *detour via* Motherwell, the distance being the same as by the old Edinburgh and Glasgow.

The increase of railways in the United States, and the principal railway engineering

* See article in another column on railways for China.

works—bridges, tunnels, viaducts etc—recently completed and in progress here and abroad were referred to in the February number of this Magazine. It is not improbable, that we are on the eve of an important reform in railway engineering especially in England, and that we shall have cheaper and competing lines, serving the public at half the present cost. As to the Goverment taking over the existing costly and extravagantly worked lines, it is at least as likely that Parliament, and more likely that Congress, will leave the whole question of railway reform to private enterprise.

The Street Railway in England.—We long since predicted, says the "Railway Record," that its adoption in the suburbs, if not in the leading streets of our own metropolis, was only a question of time, and the act passed in the last session of Parliament authorizing the laying down of street tramways in the important and populous commercial city of Liverpool gave a *coup de grace* to an opposition which had contrived to interfere with the carrying out of a vast public convenience, which has been found to answer its purpose remarkably well in Salford, and in Staffordshire, and Birkenhead. The principal of the new companies seeking Parliamentary sanction is the Tram-way Company which proposes to form eight distinct lines in, and about London. Mr. Page the architect of Westminster Bridge has prepared the designs, and the traction will be conducted either by horse or by steam locomotives. There can be no doubt that every one of these will be opposed by the existing railway interests; and whether Parliamentary sanction will be obtained, will depend upon the temper of the new House.

On the other side of the question, Mr. Hulse, President of the Manchester Institution of Engineers says in his address on cheap railways, that unless the principal streets can be widened very considerably beyond what they are, unless people become accustomed to slow traveling, and unless the danger to which horses and other vehicles are subjected in crossing the rails is removed, I fear there will not be much likelihood of street railways becoming general. In some localities, and for some special descriptions of traffic, they may be found to answer tolerably well.

Temple Bar, so long and nobly preserved by the Londoners, is at last to give way to the exigencies of street traffic.

THE CONSTRUCTION OF RESERVOIRS.

The failure of the Dale Dyke or Bradfield reservoir at Sheffield, England, in March, 1864, causing the loss of some 300 lives and immense damage to property, has led the authorities of many cities here and abroad, to look very critically into the construction and durability of similar works at their own doors. In view of the breaking of several pipes in the embankment of the Druid Lake at Baltimore, the water board of that city have called upon Messrs. J. R. Trimble, C. P. Manning and J. H. Tegmeyer, engineers, to make an examination of that work, and from their late full and able report, we extract the following interesting and timely facts and considerations.

Construction of Ancient Reservoirs in India.*—Embankments in this country have been made without puddle trenches or puddle walls, the entire material of the banks being capable of resisting water. The earth was scraped up with rude instruments or by hand, carried in small quantities by men, women and children, trodden down by the feet of workers and animals, washed by monsoon rains, and dried and baked in the sun, until after many years of slow work, a close, homogeneous, enduring mound has been formed—instead of being thrown together in bulk from carts and cars, and inadequately tempered and compressed, as by the modern system. These works are remarkable for their vast extent. One has a bank 12 miles long and a reservoir circumference of 40 miles, the conduit pipe being 60 miles long. The reservoir of Abharya-Weva, is said to have been constructed 505 years B. C. It is now partially in ruins. The lake of Minery is 20 miles in circumference; the embankment is a mile long, covered with lofty trees. It is 2,000 years old and is still in use. The Cummum Tank is one of the earliest works, to which Hindoo history refers. Its length is five miles; its breadth three miles; its area eight square miles. The top of the bank or "bund" is 102 feet above the base with an average width at top of 26 feet; inside slope 3 to 1; outside slope 1 to 1½ to 1. It has two culverts passing through it, and a waste weir of 230 feet width to carry off surplus water, but placed half a mile from the embankment.

* Mr. Rawlinson's report on the failure of the Dale Dyke Reservoir.

The Dale Dyke Embankment.—This work for enclosing the waters of the Bradfield Reservoir, was situated in the ravine of the Dale Dyke or Loxley river, 6½ miles above Sheffield, and at a point 450 feet above that town. It was erected as a storage reservoir for supplying water power to mills and factories. The water-shed or gathering area discharging water in reservoir, is 4,300 acres. When full the lake had a surface area of 78 acres. Greatest depth of embankment 95 feet; capacity 114,000 cubic feet (855,000,000 gallons); top of embankment across valley 1,254 feet long; width of base 500 feet; width at top including four feet of puddle wall, 12 feet; inner and outer slopes of banks 2½ feet horizontal to one foot vertical; puddle wall or core inside of bank sixteen feet at a bottom and four feet at top, and 95 feet high; greatest depth of puddle trench or foundation of puddle wall below natural surface 60 feet The upper 40 feet of the embankment on both sides of the puddle wall, was composed of "rubble" materials by no means water-tight. The construction of the embankment was by railway wagons and carts, with tips, in layers three to five feet high, not saturated with water during the process, nor otherwise solidified. The materials were not of a good character for the construction of a water-tight embankment; and the mode of depositing and working it was objectionable. Two lines of cast iron discharge pipes eighteen inches diameter and 1¼ inches thickness, were laid under the embankment at a point 85 feet below its top. These were the only pipes in the reservoir.

The puddle trench descended various depths to the natural rock, or below it to impervious strata. Sinking the puddle trench was a tedious and costly affair. The springs in the strata through which it was sunk were so copious as to keep two steam pumps at work for two years, day and night. The waters of the river and of floods during this time, were diverted by a catch-water reservoir, and artificial channel on the side of the valley, to intercept and turn them from the excavation. This catch-water was afterwards broken by a freshet, which filled the reservoir to a depth of 50 feet in two days. An extreme flood on the area of 4,300 acres, draining into the reservoir would give a volume of 800 cubic feet per second; two pipes of eighteen inches diameter, 500 feet long, under a head of 90 feet, would discharge 84 feet per second from it. In extreme floods 30,000 cubic feet of water per minute, would flow into the reservoir; while both drain pipes and the waste-weir working free, would discharge but 19,000 cubic feet per minute; leaving a surplus of accumulated water of 11,000 cubic feet per minute, to threaten disaster. When the breach occurred at half past eleven, on the night of 11th March, 1864, the reservoir was full and a storm prevailing. The contents were discharged through the breach in half an hour, without any previous warning; passing down the valley at the speed of 18 miles per hour and sweeping all before them.

Cause of the Failure.—The two discharges pipes were laid in a cross trench, passing under the embankment and obliquely through the main puddle wall, at a depth of about 85 feet below its top, and at a point where the puddle trench was 30 feet deep below them. They rested in a puddle trench some 30 feet deep at the lowest point under the middle of bank, and were laid in puddle only. They were laid in a manner to almost insure destruction.

The puddle wall was too thin for a work of that magnitude. The material placed on each side of the puddle wall was of too porous a character, and much of it was tipped from railroad wagons, (directly into the embankment and not afterwards distributed), which is the most objectionable manner of constructing a water-tight embankment.

The objectionable mode of laying the outlet pipes, most probably fractured the puddle wall at the point of crossing; the loose state of the materials at the top of the bank let in the water; as the water rose in the reservoir, it most probably found it way down inside the puddle wall to the fracture above the outlet pipes, and hence the destruction.

Conclusions of the English Engineers.—Cast iron pipes should never be laid under such conditions as these. A culvert of masonry with an inner valve well, should have been provided. This culvert should have been on *solid ground in the side of the valley*, free from the loose earth of the embankment. Mr. Jackson, civil engineer, called in as an expert, said that he knew of a number of cases where pipes have been fractured, but of no grand disaster like this, of fractured pipes. He has laid pipes for twenty years, but would never again lay pipes *under an embankment in any way*, although *engineers have done so from Telford's time* down to this day.

The manner is which the bank was made is condemned. The layers should not have been over two feet thick, and should have been spread and consolidated with carts. The best clay puddle should not be trusted at less than one foot of thickness for each three feet of height of water. So that for an embankment 96 feet high, the puddle wall at the base should be 32 feet thick. At Bradfield embankment the puddle at the ground line was but sixteen feet in thickness, or one-half the strength required for safety. No puddle wall should be placed between masses of porous earth, but should be backed up on both sides with at least its own thickness of well selected materials, so as to prevent direct pressure from water on the inside, or any consequent cracking on the outside. The sinking of loose materials of earth on each side of a puddle wall may do mischief, unless such settlement takes place equally, evenly and slowly. A puddle wall should be wetted, worked and tempered into proper consistency. If the material on each side is not of the same sort and consistency, and does not set or build with the puddle, the bank is liable to injury.

If a deep trench continues to produce water, such water will soften the puddle and cause fracture of the puddle wall. Springs in the side of a puddle trench will inevitaaly waste and wash such puddle, unless special means are provided to divert the water. Undisturbed strata may bear and resist water safely—when, if broken and disturbed by deep sinking and heavy continued pumping for the formation of a puddle trench, the whole strata may be so ruptured, washed and disturbed as never again to become sound. A perfectly homogeneous bank on a stable substratum is alone safe. A puddle wall may be "a delusion and a snare."

Conclusions of the American Engineers, on Puddling.—It is a matter of much surprise to any one not trained and educated in the English school of Hydraulic Engineers, to find so little improvement has been made in that country for the last hundred years in the mode of preparing and applying puddle material. The English adhere tenaciously, and often blindly, to old customs and to the practice of early and eminent engineers. The evidence taken before the coroner's jury shows that errors in plan and construction have been followed from Telford down to the present day—errors now admitted to be plain, though heretofore undiscovered.

The early English engineers used "cut puddling," called so from layers of clay cut out of carefully selected material by the spade and packed carefully in the puddle wall as carried up with wetting, but not thorough saturation, to bind the material into one mass. The method of puddling by throwing materials into water, or by flooding the material already placed, called "flood puddling," originated in the United States, and was probably used first on the Baltimore Water Works, or, if used in England it was unknown to American engineers. Its advantages have been so manifest in practice that in our opinion it is immeasurably superior to all other methods, and should be adopted to the exclusion of old processes. When we reflect that water exerts an agency everywhere in causing loose earth to take a compact form in our fields, roads and common embankments, it needs no labored argument to prove that there is no process which can so soon and so effectually bring a reservoir embankment to the required condition of homogenous compactness. It must all be alike in consistency, without any part subjected to the risk of being left dry and porous, to subside unevenly.

The Druid Lake Works.—The Druid Hill Reservoir is made in a dry ravine, with an area of less than 100 acres to gather floods. It will have a bank of 60 feet width on top, with an exterior slope of 2 to 1, and an interior slope of 4 to 1, giving a thickness at base of 650 feet. The embankment has a puddle wall of 95 feet extreme height above natural surface, or 119 feet above the lowest foundation of puddle trench; a thickness at top of 17 feet and 36 feet at bottom. The firm deposits of ages from the hills of Druid Park collected in the ravine, are mixtures of clay and gravel, constituting an impervious stratum, which was properly left undisturbed in the construction of the reservoir, except to remove vegetable matter, &c., to about one foot in depth. The puddle trench was but 12 feet in depth to impervious strata of rock in the bottom of the ravine, without any springs and but a slight filtration of water, in fact, dry. The formation of the embankment was from clay, earth and decomposed gneiss and disintegrated granite, the gneiss supplying a pure clay from decomposed feldspar, and gravel from the quartz and mica happily blended, so as to ensure impermeability by its adhesiveness, and solidity by its compactness and specific gravity.

As to the fracture of the pipes in these works, and proposed changes, the report states: The first pipe fractured badly was the drain pipe, discovered twelve months after it was laid. In the fall of the same year (1866), the three influent pipes were found so badly injured as to render necessary their abandonment from prudential motives. The nature of the fractures were cracks at the bell-ends and from end to end and across the pipe, in some instances. These ruptures were first discovered by finding at a point just outside the embankment a small leakage of water discolored with iron. The roundness of the pipes was in some cases destroyed. Although these pipes were carefully laid in the manner frequently adopted elsewhere, yet four out of the seven have failed.

The engineers now consider the mode of laying these pipes objectionable, and their location under the bank injudicious. Pipes laid anywhere should rest on a foundation of perfectly uniform resistance, to preclude the possibility of unequal settling, which must fracture cast-iron. A perfectly solid basis would seem to be safest. The error committed was in laying part of the length in trenches and a part on piers. With so great a height of embankment above them, subsiding all the time, it could not be expected that either the pressure of the bank or the resistance of the foundations would be uniform. A slight difference in either would fracture the pipes. Those pipes remaining sound so far, must have had a uniform pressure upon them, or have presented a uniform resistance, so that no one part yielded more than another. But as we now see from experience in England, it would have been better to insert all the pipes in the reservoir through *solid ground above the embankment and remote from the puddle wall.*

This change, suggested by Mr. Wendell Bollman, "will have to be made." The cluster of four pipes is to be carried, through solid ground at a level of 60 feet below the contemplated high water lines of the reservoir, built on carefully prepared foundations, and enclosed in stone and cement, with several projecting collars of masonry to check leakage and obstruct any flow of water.* Each pipe is to be enclosed in a brick culvert, fitting tightly its outer surface, so that when in time the iron is destroyed from any cause, the enclosing arch shall form a permanent conduit in place of the pipe.

* See on this subject, Hon. Wm. J. McAlpine's paper, Van Nostrand's Magazine, Vol. 1, No. 1, page 10.

ORDNANCE EXPERIMENTS—NEW ENGLISH BOARD.—In view of the complaints of inventors, the defenses of Ordnance Boards and officers, and the present excitement on these questions among persons interested in ordnance improvement, no less in America than in England, the following, from the "Army and Navy Gazette" will be of interest. For some time the Ordnance Select Committee has ceased to exist, and few will regret its demise. It had many enemies, and was regarded with suspicion even by those to whom it was most favorable. It was confessedly an expensive body in itself, and was the cause and origin of much expense in experiments which were often supposed to be instituted more with a view to investigate the mathematical and theoretical value of inventions, than their practical utility to the service. Since the Ordnance Select Committee received its death-blow, the constitution of its successor has been much discussed, and several attempts have been made to arrange its composition. These have mostly proved abortive, but we believe that the future tribunals before which both inventors and inventions will be arraigned have been practically settled. The present committee which is engaged in investigating Captain Moncrieff's battery, and the proper emolument to be conferred upon its designer, will probably decide all broad questions of the same kind in future. This committee is composed of the Parliamentary Under-Secretary of State for War, the Comptroller-in-Chief, the Naval Director of Ordnance, the Director of Works, the Director-General of Ordnance and the Assistant-Director; and its province is to decide broad questions and general principles.

To carry out experiments and inquire into details, either a special committee will be assembled, as has been done in the case of deciding upon the new breech-loading rifle, and the armament of field artillery for India, or, in less important cases, the matter will be submitted to the consideration of a permanent committee of inventions. The committee of inventions will be for the present composed of Colonel Milward, R.A., C.B.; Colonel Shaw, R.A.; Colonel Wray, R.A. (late Bombay Artillery); Lieutenant-Colonel Heyman, R.A.; with Captain Harrison as secretary. By this reorganisation of the duties of the Ordnance Select Committee, a great improvement will be probably effected, and great dissatisfaction will be removed; for there is no doubt that, justly or unjustly, the late Ordnance Select Committee was suspected by the outside world to be composed too exclusively of officers of scientific tendencies, interested in inventions, who were not inclined to view with favor or even impartiality, inventions which did not originate among their own adherents. The new Ordnance Board will, however, be far above any such suspicion; and, as its members sit *ex-officio* it is almost certain to remain so. A tribunal will thus be secured which will be, if not always satisfactory to inventors, open to no suspicion of favor, partiality or affection, while the country will find in it an adequate, competent and inexpensive arbiter of what is requisite for its necessities, as the members will receive no additional emolument for their services in this capacity.

THE HOLYOKE DAM.—The dam across the Connecticut River at Holyoke, Mass., having an unbroken length of upwards of 1,000 feet and with the water pouring over it in a massive sheet with a fall of 30 feet, has long constituted one of the most noteworthy of the many objects of interest in that portion of the country. The picturesque aspect is, however, doomed to be done away with, for the wear of the waters upon the soft rock at the base of the dam has hollowed it out to a depth of from six to eight yards, thus endangering the foundations of the structure and necessitating repairs which amount practically to thorough reconstruction, and which will change the waterfall into swift rapids shooting down an artificial inclined plane.

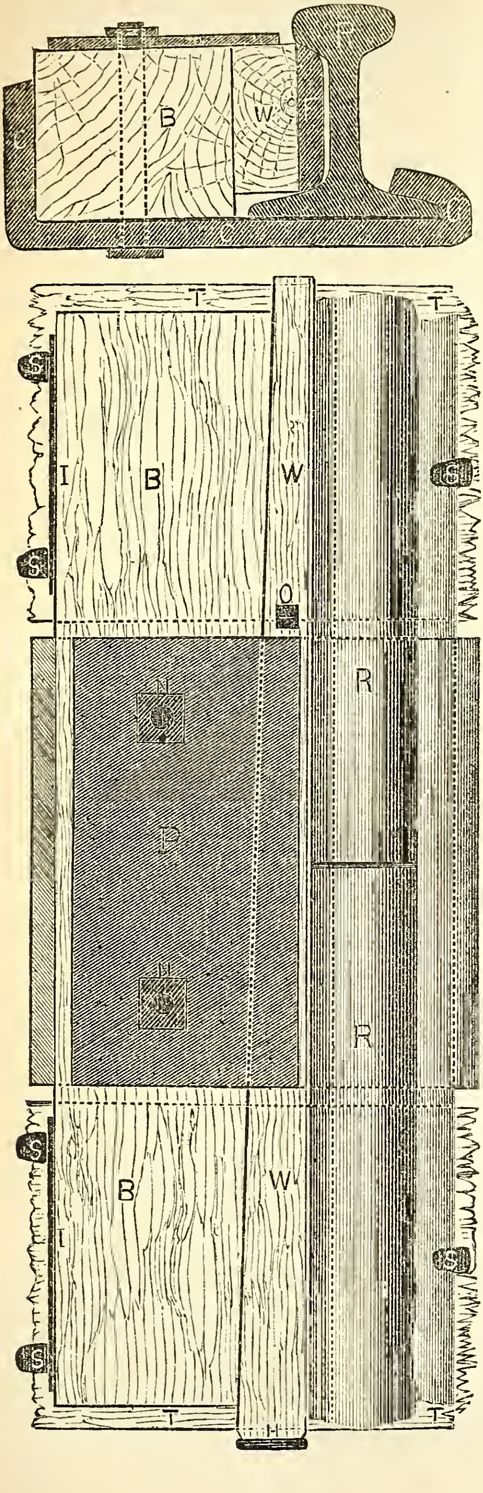
The process of repair is now being carried on with great energy, a portion 279 feet long at the centre of the dam having been already completed. For a distance of 50 feet down the stream, a series of timbers, locked and framed one over another, have been laid, and their interstices filled with stone. These from the bed of the stream rise to a height of twenty-five feet to the surface of the water. From the front edge of the substructure thus formed, the frame-work is continued with an inclined surface until it reaches the crest of the dam 30 feet above. This solid mass of stone and timber is covered with square logs a foot in diameter, and pinned fast to the timbers underneath; upon these are spiked maple planks four inches thick, which make the covering for the whole. The crest of the dam for a width of five feet is designed to be covered with three-sixteenths boiler-plate, of which not less than sixteen tons will have been used by the time the work is finished.

The portion or section of the dam of which we have just spoken has alone required about one million feet of lumber, eight thousand square rods of stone, and fifteen tons of bolts. The weight of the entire structure is estimated at thirty-three tons. The weight of that part of the dam is capable of resisting about four times the ordinary pressure of the water upon it.—*American Artisan.*

JAMES CHALMERS.—If the inventor of the best system of armor plating, could have enjoyed, while he was toiling for a trial of his scheme, a little more of that good English feeling and appreciation that the London newspapers are bestowing now that he is dead, it would have been better for all concerned. The system of backing armor plates by a cell-work of thin wrought iron plates, first introduced by Mr. Chalmers, has been improved only in size and detail, and is now the principle upon which every successful target is constructed. Mr. Chalmers' first target was not constructed at Government expense, but at the expense of Sir S. M. Peto. After its successful trial, says the "Army and Navy Gazette:" Mr. Chalmers suffered the mortification of seeing many of the essentials of his inventions copied and embodied in the recent additions to the Navy, without either acknowledgment or compensation; and, notwithstanding all his endeavors, he was never able, till lately, to prevail on the Government to get another target built embodying his invention, to be tried against a Government one of the same size and weight of metal. In this, careworn and wearied by official obstructions and delays, his naturally strong constitution gave way, and during the last eighteen months his health had been far from good, till at last he died on the 26th of December, at his residence in London.

Mr. Chalmers was also the author of a scheme of sunken channel railway, between England and France. His plan was, to have a tube of boiler plate, lined with brick, laid on the bottom of the sea, with ventilating towers at intervals; and the pamphlet which he published on the subject attracted general attention, and no small amount of criticism at the time.

FOSTER'S RAIL JOINT.



Now that the subject of maintaining the continuity of rails, is receiving general attention in this country, we shall publish from time to time, the particulars and results of such new devices as have been well tested, or are obviously practicable.

The joint fastening shown in the cuts, is the invention of Mr. Foster, Superintendent of the Logansport, Peoria and Burlington railway. It has grown out of his observation of the remarkable wear of several pieces of track which had to be laid in a peculiar manner owing to local causes; the rails were practically sandwiched at the joints, and have outworn several similar rails laid in the common manner. About ten tons of these joints have been under practical test during two years past on the road mentioned, also on the Chicago and Great Eastern, upon tracks used in common by the several roads centering at Logansport, also upon sidings where a large amount of shifting is done; locomotives run over the joints 200 to 300 times per day. The results are extremely satisfactory, when compared with all forms of chairs; the report does not state, however, whether it has been compared with the best of the modern fastenings. The lateral as well as the vertical continuity of the track is well preserved. A great saving in repairs is clearly shown. No stops, O, have been placed upon the wedges, but out of the whole ten tons, but two have got loose. Experiments have shown that the joint has less deflection under a passing load than the solid rail.

The most economical and effective form of splice, when the rail is suitably shaped, is the fish bar between the head and flange. How to keep the fish bar tight, has taxed the ingenuity of inventors for some twenty years. In this case, it is held up to the rail by an oak wedge, W, bearing upon the whole face of the fish bar, and hence not likely either to mash or to slip. With a rail of the form shown (in distinction from the low "pear head"), and a stiff clamp, C, the fish is certain to remain tightly wedged between the tables of the rail, and to be fully utilized. The lip of the clamp C is also wedged tightly upon the flange of the rail by the same wedge that secures the fish plate, thus realizing in some degree the advantage of the new Reeves' joint, which is a tight clamp upon the flanges of the rail. The clamp C and the wooden longitudinal B also add a considerable resistance to deflection; but the chief office of the longitudinal is to form a backing for the wedge. The joint is suspended between two sleepers, thus giving ample elasticity, and also preventing the "creeping" of the track. Ths wood (oak) is seasoned, soaked in oil, planed, and carefully adjusted.

The best feature of this joint is the security of the fastening—the long wedge will not slip, though it may be readily set up; and its strength is a simple question of size of wedge and longitudinal. The joint is adapted to every form of rail, and may thus improve tracks that cannot be fished to advantage. It is well adapted to steel rails, because it requires no nicking or punching of the rails, either to prevent "creeping" or to hold the fish bar in place.

Iron Architecture.—From a historical article on this subject in "Engineering," we gather the following facts: In 1783 Robert Ransome patented the application of cast iron, variously ornamented, to roofs. Twenty-five years later, Ralph Dodd obtained a patent for applications of iron to floors and to ship work, including hollow columns. Several patents followed for the substitution of iron for timber work. In 1811 Thomas Pearsall patented the use of iron skeletons—standards, joists, &c.—to be filled in with brick work. Ten years later iron beams were first employed for fire-proof floors, at a cotton mill in Manchester. In 1834 Pearsall's iron skeleton, covered with iron sheets, was applied in the erection of a gas works in London; and in 1842 Messrs. Laycock, of Manchester, constructed an iron palace, fifty feet by thirty feet, and three stories high, for the King of Eyamba, on the Calabar river. About this time Messrs. Gussell were making iron buildings for erection abroad; iron frames and corrugated sheet-iron covering, and shortly afterwards, the manufacture of portable iron houses largely increased. In 1845, Mr. W. Vose Pickett formed a company to erect iron buildings, and was the first to advocate the use of the cellular form of construction, and the ornamentation of pannels to resemble stone. But with the exception of the Great Exhibition buildings of 1851 and 1862, and a few large structures for special purposes, and some mere sheds without ornament, the use of iron for building—for street architecuture—has been singularly neglected in England.

In the United States, on the contrary, thousands of iron structures have been erected, and such is their design that iron façades can hardly be distinguished from stone. The first of these buildings was put up by Daniel D Badger, of New York, in 1842. In the following year A. L. Johnson, of Baltimore, introduced revolving iron shutters, and by a combination of these with iron posts, the lower stories of commercial buildings came to be generally made of the new material. About this time James Bogardus, of New York, was working succesfully in the same direction, and in 1847 he erected his lofty iron factory, which was subsequently taken down and re-erected, on account of the widening of a street. The Architectural Iron Works of New York and other American cities, are now very numerous, one of the latest and most prosperous being a branch of the Novelty Iron Works. Some 150 iron buildings appear in Broadway, and the use of this material appears to be largely increasing.

The Leavenworth Bridge.—A contract for the construction of a bridge over the Kansas river at Leavenworth, has been definitely concluded with that eminent bridge builder, L. B. Boomer, Esq. The bridge is to be completed for both railway and highway traffic in twelve months, at a cost of three-quarters of a million of dollars. The main bridge will consist either of three spans of 340 feet each, or four spans of 258 feet each, the superstructure to be of iron, upon the plan known as the "Post's Patent Inflexible Truss." The west abutment will be of first-class masonry; the rest of the substructure of cast iron pneumatic piles or cylinders, each $8\frac{1}{2}$ feet in diameter, to be driven to the rock (about 60 feet below low water mark,) and carried up to the bridge seat, the whole height from rock to bridge seat being about 135 feet.

These columns are to be filled with cement and will be thoroughly braced to each other, and each pier will have an iron ice-breaker supported by another cylinder driven to the rock and brought up to low water mark. The approaches (about 4,000 feet long,) are to be built of wooden trestles.—*Chicago Railway Review.*

EXPERIMENTAL RESEARCHES ON THE MECHANICAL PROPERTIES OF STEEL.

By Wm. Fairbairn, L.L.D., F.R.S., &c.

From the "Quarterly Journal of Science."

The present may be justly considered the age of iron, as in every branch of industry where force, form, and motion are required, iron enters largely into construction, and its powers of application have supplanted almost every other material. It presents wonderful facilities in its adaptation to every description of art, whether of the useful or decorative style ; and its improved tenacity, elasticity and ductility have enlarged its field of usefulness in the construction of buildings, ships, steam-engines, bridges, and machinery of all sorts where strength combined with lightness is required. To this powerful and valuable material we are indebted for railways, locomotives, and rolling stock ; and there is no branch of manufacture in which it does not form a whole or a prominent part. Possessed of such a material in its cheapest and best forms, we should be deficient in duty if we left it in the rude state in which it was found in the days of Cort and his immediate successors. That great improvements have been effected of late years does not admit of doubt, and there is probably no material that has undergone greater changes in its manufacture than iron ; and judging from the attempts that are now making, and have been made, to improve its quality and to enlarge its sphere of application, we may reasonably conclude that it is destined to attain still greater advances in its chemical and mechanical properties. The earliest improvements in the process of the manufacture of iron may be attributed to Cort, who introduced the process of boiling and puddling in the reverberatory furnace, and those of more recent date to Bessemer, who first used a separate vessel for the reduction of the metals, and thus effected more important changes in the manufacture of iron and steel than had been introduced at any former period in metallurgic history. To the latter system we owe most of the improvements that have taken place ; for by the comparatively new and interesting process of burning out the carbon in a separate vessel, almost every description of steel and refined iron may be produced. The same results may be obtained by the puddling-furnace, but not to the same extent, since the artificial blast of the Bessemer principle acts with much greater force in depriving the metal of its carbon, and in reducing it to the state of refined iron. By this new process increased facilities are afforded for attaining new combinations, by the introduction of measured quantities of carbon into the converting vessel, and this may be so regulated as to form steel or iron of the homogeneous state, of any known quality.

The production of iron and steel in the homogeneous state is one of the most important improvements that has taken place since the process of rolling direct from the reverberatory furnace. The former process was first to melt the iron as it came from the smelting-furnace in the shape of pigs, to puddle it or to stir it about until the mass took the form of a ball deprived of its carbon ; it was then placed under the hammer, and formed into slabs or ingots The next process was to roll it into bars, which being cut into short pieces, were again heated and rolled either into plates or bars as required.

Now the great defect of this process was the unsound state of the iron, as the least rust or scoriæ on the surface of the piled bars prevented the welding or fusion of the metals, and hence followed what are called blistered plates, or laminated bars of unsound construction.

The new process, it will be observed, obviates all these difficulties, as in the Bessemer process the melted iron is deprived of its carbon by the action of an artificial blast—the same as formerly prevailed on the hearth of the refinery—and thence it is cast into ingots of the weight required, either for the hammer or the rolls. From this it will be seen that the risk of piling and welding is entirely dispensed with, and the article produced, whether of iron or steel, is perfect in its homogeneity. It may be of good or inferior quality, hard or soft, but by this process it is free from the risk of being unsound in its homogeneous state.

As regards the steel, of which we have to submit the results, as produced by the principal manufacturers of this country, it will be observed that in making steel from the puddling-furnace, similar combinations may be produced, but with less certainty as regards quality, as everything depends on the skill of the operator in closing the furnace at the precise moment of time, before the mass is deprived of its carbon. This precaution is necessary in order to retain the exact quantity of carbon in the puddled ball, so as to produce by combination the requisite quality of steel. It will be observed that in the Bessemer process this uncertainty does not exist, as the whole of the carbon is volatilized or burnt out in the first instance; and by pouring into the vessel a certain quantity of crude metal containing carbon, any percentage of that element may be obtained in combination with the iron, possessing qualities best adapted to the varied forms of construction to which it may be applied. Thus the Bessemer process is not only more perfect in itself, but admits of a greater degree of certainty in the results than could possibly be attained by the mere employment of the eyes and hands of the most experienced puddler. Thus it appears that the Bessemer process enables us to manufacture steel with any given proportion of carbon, or other eligible element, and thus to describe the compound metal in terms of its chemical constituents.

Important changes have been made since Mr. Bessemer first announced his new principle of conversion, and the results obtained from various quarters bid fair to establish a new epoch in metallurgic manipulation, by the production of a material of much greater general value than that which was produced by the old process, and in most cases of double the strength of iron.

These improvements are not exclusively confined to the Bessemer process, for a great variety of processes are now in operation producing the same results, and hence we have now in the market homogeneous and every other description of iron, inclusive of steel, of such density, ductility, etc., as to meet all the requirements of the varied forms of construction.

The chemical properties of these different kinds of steel have been satisfactorily established; but we have no reliable knowledge of the mechanical properties of the different descriptions of homogeneous iron and steel that are now being produced. To supply this desideratum, I have endeavored, by a series of elaborate experiments, to determine the comparative values of the different kinds of steel, as regards their powers of resistance to transverse, tensile, and compressive strain.

These experiments have been instituted not only for those engaged in the constructive arts, but also to enable the engineer to make selections of the material as will best suit his purpose in any work proposed. In order to arrive at correct results, I have applied to the first houses for the specimens experimented upon, and judging from the results of these experiments, I venture to hope that new and important data have been obtained, which may safely be relied upon in the selection of the material for the different forms of construction.

For several years past, attempts have been made to substitute steel for iron, on account of its superior tenacity in the construction of ships, boilers, bridges, etc.; and there can be no doubt as to the desirability of employing a material of the same weight and of double the strength, provided it can at all times be relied upon. Some difficulties, however, exist, and until they are removed it would not be safe to make the transfer from iron to steel. These difficulties may be summed up in a few words, viz: the want of uniformity in the manufacture, in cases of rolled plates and other articles, which require perfect resemblance in character, and the uncertainty which pervades its production. Time and a close observation of facts in connection with the different processes will, however, surmount these difficulties, and will enable the manufacturer to produce steel in all its varieties with the same certainty as he formerly attained in the manufacture of iron.

In the selection of the different specimens of steel, I have endeavored to obtain such information about the ores, fuel and process of manufacture as the parties supplying the specimens were disposed to furnish. To a series of questions, answers were, in most cases, cheerfully given, the particulars of which will be found in the experimental tables, published in the Transactions of the British Association for 1867.

I have intimated that the specimens have been submitted to transverse, tensile, and compressive strain, and the summaries of results will indicate the uses to which the different specimens may be applied. Table I. gives for each specimen the modulus of elasticity, and the modulus of resistance to impact, together with the deflection for unity of pressure; from these experimental data the engineer and architect may select the steel possessing the actual quality required for any particular structure. This will be found especially requisite in the construction of boilers, ships, bridges, and other structures subjected to severe strains, where safety, strength, and economy should be kept in view.

In the case of transverse strain some difficulties presented themselves in the cours of the experiments, arising from the ductil .

nature of some part of the material, and from its tendency to bend or deflect to a considerable depth without fracture.

But this is always the case with tough bars, whether of iron or steel, and hence the necessity of fixing upon some unit of measure of the deflections, in order to compare the flexibility of the bars with one another, and, from the mean value of this unit of deflection, to obtain a mean value of the modulus of elasticity (E) for the different bars. This unit or measure of flexibility given in the table, is the mean value all the deflections corresponding to unity of pressure and section. In order to determine the resistance of the bars to a force analogous to that of impact, *the work* in deflecting each bar up to its limit of elasticity has been calculated. These results differ considerably from each other, showing the different degree of hardness, ductility, etc., of the material of which the bars are composed. The transverse strength of the different bars up to their limit of elasticity is shown by the amount of the *modulus of strength* or *the unit of strength* calculated for each bar.

Table II, on Tensile Strain, gives the breaking-strain of each bar per square inch of section, and the corresponding elongation of the bar per unit of length, together with the ultimate resistance of each bar to a force analogous to that of impact.

Table III, on Compression, gives the force per square inch of section requisite to crush short columns of the different specimens, with the corresponding compression of the column per unit of length, together with the work expended in producing this compression.

It will be observed from the following tables that the results of the experiments show that the deflections produced by a transverse strain are in proportion to the pressures within the limits of elasticity.

In Table I, as in the other two on tension and compression, the value of the work done on each specimen has been determined, and the results recorded in the last column indicate the comparative strength of each particular bar; and the mean value of the deflections corresponding to unity of pressure and section will be found in column 3. These may be taken as the measure of flexibility, elasticity, and ductility of the different bars, and the uses to which the material may be applied.

The mean value of E, the modulus of elasticity taken for thirty of the best specimens, is about 31,000,000, which exceeds that of wrought iron by more than the thirtieth part. Steel having a much greater flexibility than malleable iron, accounts for the approximation of their respective values in D. This arises from the fact that the bars of the greatest flexibility—other things being the same—have the least value for the modulus of elasticity.

On tensile strain the mean result derived from thirty of the best specimens is 47.7 tons, or nearly 48 tons per square inch; and in this, as in the previous table, the measure of ductility and strength is given in the last column, which indicates the ultility of the material and the purposes for which it may be selected.

Comparing the best quality of steel with the best wrought iron at 24 tons as the breaking-weight per square inch, we find that we have a material of double the strength with the same weight, or what is the same thing, of only half the weight with the same same strength, or as 47.7 to 24. In the art of construction these are considerations of great importance; and in every case where steel can be depended upon, it is entitled, on the score of economy and lightness, to the judgement and practical knowledge of the architect and engineer.

In Table III, on compression, each of the specimens were reduced, when cut from the bars previously experimented upon, to small columns of $\frac{3}{4}$ inch diameter and 1 inch in height. They were each loaded with weights equal to 100 tons per square inch, without undergoing any sensible appearance of fracture. On consulting the table it will be found that with the above weight of 100 tons per square inch they were compressed, on the average, to two-thirds their original length; and from these facts we were enabled to find the value of u, recorded in the last column, as the value of work done by the load which produced the change of form in each of the specimens submitted to pressure. This, it will be observed, was the true test of the powers of resistance of the respective specimens to a compressive strain, and the conditions under which materials of similar properties may be safely applied in constructive art.

On comparing the mean tensile resistance to rupture at 47.7 tons per square inch, it will be seen that the resistance to compression is more than double the resistance to extension, or as 100.7 to 47.47, being in the ratio of near 2:1. Hence it follows that the most economic form of a steel bar un-

dergoing a transverse strain would be a bar with double flanges, having the area of the top flange about one-half that of the bottom.

This conclusion is borne out by the results of experiments on transverse strain, where S_1, the strain per square inch of the material at the elastic limit, $= 6\ C = 6 \times 6.83$ tons $= 40.98$, or 41 tons nearly; but the mean breaking-strain per square inch by extension $= 47.7$ tons, clearly indicates that the compressive resistance in the former case was considerably in excess of the tensile resistance.

It is important in every experiment on the strength of materials, which enters so largely into constructive art, that we should be thoroughly acquainted with the properties of the material of which the structure is composed, and that its resistance in all the different forms of strain should be clearly and distinctly ascertained. In the foregoing experiments we have determined the resisting powers of the different specimens to bending, tension, and compression; but we have omitted that of torsion, or twisting, until we have an opportunity of doing so upon the same identical bars. These I hope to accomplish at some future period, and also to give some further results upon an enlarged scale, calculated to confirm what has already been done, and to ascertain some additional facts in regard to the changes now in progress in the manufacture of Iron and Steel.

THE PNEUMATIC DESPATCH.

This thoroughly practical, speedy and cheap means of transporting parcels, if not passengers, having been placed under a temporary cloud by the financial difficulties of the London Company that are building it on the largest scale, is is about to be revived and pushed to completion. Says "Engineering": Some five years ago the Pneumatic Despatch Company commenced the construction of a line from Euston station to Holborn, and thence to the General Post-office. The first length, from Euston square to Holborn, was completed in the autumn of 1865, and in the October and November of that year many experimental trains were despatched through the tube with success. The experimental working, however, lasted for a weeks only, and eventually, pecuniary difficulties arising, the works were closed. Things remained in this state until a few weeks ago, when arrangements were made to complete the line. The length from the Euston station to Holborn is 1¾ miles, while a short length has also been laid from the Holborn station eastward, and this latter length is now to be extended to the General Post-office.

For the greater part of its length the line consists of cast-iron tubes 4 ft. 6 in. wide by 4 ft. high, these tubes being made in 9 ft. lengths, and the joints between them being caulked with lead. Besides curves of moderately large radius the line comprises a curve of 170 ft. radius, at the corner of Drummond-street and the Hampstead-road, a similar curve where the line turns eastward at Broad-street, St. Giles's, and a curve of 70 ft. radius where it enters the Holborn station. On these curves the tube is constructed of brickwork.

At the Holborn station are situated a pair of horizontal engines with 24 in. cylinders and 20 in. stroke, which work the fan 22 ft. in diameter, by which the air is exhausted from and forced into the tubes. The trains will be drawn from the termini to the Holborn station by exhausting the air in the tube, and forced from the Holborn station to the termini by the opposite process. The carriages, or trucks, are carried on four wheels, and their ends are shaped so that they almost fit the tube, the slight clearance allowed being partially closed by projecting strips of sheet india-rubber. The suction main is connected with each main tube at some distance from the end, and the carriages, on passing the mouth of the suction tube, have their motion arrested by the cushion of air formed between them and the doors, by which the end of the main tube is closed. At the proper moment these doors are opened by a self-acting arrangement, allowing the train to pass through. At the Holborn station the ends of the two main tubes, the one from Euston and the other (which is yet to be completed) from the Post-office are situated side by side, and a traverser is provided by which the trucks can be rapidly transferred from the one tube to the other. It is expected that the total time occupied in the transit from the Euston station to the Post-office will be about from 13 to 15 minutes; the time occupied by the experimental trains in running from Euston station to Holborn being 7 minutes.

Of the progress of a similar work in New York, the "New York Times" says that a company of English capitalists, have obtained a charter from the Legislature and have commenced to construct a pneumatic dispatch-tube in the lower part of the City, for the conveyance of parcels and letters, and it might be, passengers also. Mr. Moses Beach, the president of the company, hired the basement of the Messrs. Devlin's store, corner of Broadway and Murray-street, as a starting point for the line, with the intention of carrying it to the vicinity of the Nassau-street Post-office. The work of tunneling beneath Broadway then begun, has been slowly but steadily progressing, and will be pushed forward to completion as soon as possible. The details of the company have been carefully withheld from the public, in order to avoid the otherwise inevitable annoyance of injunctions from stage-line proprietors and property-owners on the route.

VIS VIVA.—"With a double velocity the moving (railway) train passes over double the space each second, and therefore encounters twice as many points of resistance. Moreover, it strikes each of these points with double the velocity, and hence meets at each point twice the resistance. It therefore meets, during a second, twice as many points of resistance, and suffers at each point twice as much resistance. The resistance, during a second, is thus four times as great as before, and must require four times as much force to overcome it. In order to obtain three times the velocity it would be necessary to increase by nine times the force; and in general the force required will be proportional to the square of the velocity to be obtained. What is true of the motion of the train of cars is true also of the motion of a steamboat through the water, and indeed of any motion on the surface of the earth, since all such motions encounter resistance. Hence the work accomplished by a force is proportional, not to the velocity, but to the square of the velocity, which it imparts to the moving body." (Cook's Chemical Physics, page 52.) Prof. Cook continues, upon such a basis, to explain *vis viva* and *momentum*. Most of the school-books on physics and natural philosophy present the subject in a similar way, and we have quoted from Cook's Chemical Physics simply because it is a work of the very highest repute for accuracy of statement of facts and theories, and therefore cannot be objected to as a representative.

In our present judgment the statements above quoted are not sustained by reason or experience. It is very far, indeed, from true, as a question of fact, that the power required to maintain a train or a ship in uniform motion varies as the square of the velocity; there is really no such mathematical relation, and there is no close approximation to it; moreover, the case of a ship is so different from that of the train that many engineers who strive to measure facts on a procrustean bed of simple mathematical formulæ, represent that the power required to drive a ship varies as the cube of the velocity; and no experienced engineer will say that within ordinary limits of speed four times as much power is ever required to maintain a train at double velocity. Professor Cook indeed represents that the resistances in a double velocity are doubled at each point, but this is surely an assumption, and is not warranted by experience. The resistances to a train in motion are mainly friction, and the air to be pushed aside; the friction is nearly proportioned to space and not to velocity, while a law of the resistance of the air is practically indeterminable. Now we have to suggest that the confusion and mystery of the subject, at least so far as the theory is concerned, are avoided by considering the work done as the measure of force or power. If we wish to determine only the *quantity* of effective force concerned in a movement, it is quite independent of time or velocity; the raising a pound of matter one foot implies always the same amount of moving force, power, or actual energy, whether it has occupied an instant or an age. Double work imples double power; to grind two bushels of corn requires twice the power to grind one. When resistances to motion are uniform, the space gone over measures the work and the power irrespective of time and velocity. If in any case the total quantity of resistance varies with velocity, then the power to maintain uniform motion will vary with the square of the velocity; but is there really such a case in nature or in art? A locomotive engine makes a certain number of strokes (excepting the slip) per mile, whether moving fast or slow. which represent the same number of cylinders full of steam, and, except for the resistance of the air, the cost per mile of running would be nearly the same for all velocities.

It should be noted that we carefully distinguish the cases of maintaining a uniform motion and the changing of velocity. In case of regular change (acceleration or retardation), as in the free fall of bodies by gravity, the spaces gone over are a measure of kinetic energy and vary with the square of the velocity; for example, to double the acquired velocity requires quadruple the power. It requires about four times the space and four times the steam to attain from rest a double velocity of a locomotive, but when the velocity is attained we have done with the ratio of the squares. The principle of *vis viva*, as we understand it, applies only to the changing of velocity.—*Chemical News.*

BREAKING IRON AND STEEL MASSES.

"Armengaud's Génie Industrille" through "Dingler's Polyt. Journal." Translated by John B. Pearse.

Pieces of cast iron of considerable size are extremely difficult to break up, and necessitate colossal air furnaces in order to melt them without breaking. The following method of breaking up large pieces has been practiced successfully at the works of Petin and Gaudet in Saint Chamond. Powder is often used to divide large masses, but aside from the necessary caution, its use is difficult and it often does not accomplish the desired effect. The following method, invented by M. Montandon, manager of the above works, is quite easy to apply, and not at all dangerous. It consists in using the force, which confined water exerts (when struck), in every direction upon the material in which it is enclosed.

A round hole two to three inches in diameter and ten to twelve inches deep is bored in the mass to be split; this hole is then filled with water and closed by a closely fitting steel cylinder upon which the drop is allowed to fall from the usual height. The mass is thereby split into several pieces, as if by a strong wedge with several faces. The water cannot escape and its endeavor to do so bursts the metal. In this way a plate roll of 29½ inches diameter was split, in presence of the French editor, into four or five pieces, which flew 20 to 30 feet away from the drop.

The hole must be hermetically closed and in order to do this thoroughly it is necessary to hollow out the base of the steel cylinder into a cup shaped form, the edges of which are driven against the walls of the hole by the water in its efforts to get past. To allow the air under the pin to escape, it is well to file a small screw-shaped grooved on the latter, when it can be driven down quite easily.

A single blow of an ordinary drop usually suffices to split off pieces of 30 to 36 inches in diameter. A pin of good steel can be used several times. This method is obviously easier than the use of a large drop falling a great distance and is much more certain in its effects.

SANITARY ENGINEERING.—In addition to watering and draining towns, the engineer is now called upon to provide fresh air artificially—to ventilate not only buildings, but whole towns. This subject was mentioned by Dr. Rumsey, in a recent address to the National Association for the promotion of social science, in England.

IRON AND STEEL NOTES.

INFLUENCE OF THE OXIDES OF CHROMIUM AND TITANIUM ON THE COMPOSITION OF PIG IRON.—Within the last four years we have been frequently employed in chemical investigations of the altered characters of some pig irons, which resulted apparently under the usual circumstances in the reduction of uniform ore. In these cases the amount of carbon united with the iron had been diminished, without the introduction of other matter in quantity sufficient to influence a change in this connection, and generally no variation in the composition of the ore was known or suspected. We had analyzed the ores in some of the beds in former years, and regarded them as well adapted to the production of pig iron of good quality; but, in pursuing the research, we were convinced that the change in quality of iron could be traced to altered composition in the ore of part of the beds used for supplying the furnaces.

The correctness of this view was confirmed by our analyses of many iron ores, in some of which we found the oxides of chromium or titanium, existing where they were not indicated and connected with the ore in beds which have been considered as pure iron ores. Both the oxide of chromium and oxide of titanium seem to act in the furnace or the crucible in a way to withdraw a portion of the carbon, or prevent that true union of carbon with a portion of the iron, which constitutes gray pig iron, without the metals of these oxides really alloying with the iron and thus indicating the cause of change. We have analyzed samples of pig iron where the alloys of chromium or titanium existed in the pigs, and where the oxides accompanied the ores in the beds, but we were not prepared to find an influence exerted on the quality of the pig metal *without the refractory metals forming a part of the composition.*

The occurrence of oxide of magneso with iron ore is common, and titanium compounds are often found in both magnetic and brown iron ores, as insoluble substances, in small proportions, and these compounds combine with and are removed by the fluxes without injury to the pig metal. These compounds of titanium are the cause of the often superb blue color of the cinder, produced under varying conditions of glassy or stony character, and must be carefully distinguished from those we regard as more detrimental in their influence on the metal.

In a number of analyses of iron ores we had found both oxide of chromium and oxide of titanium in a state rendering them soluble in diluted acids, and in a condition to escape detection in the ordinary modes of analysis. Both magnetic and brown iron ores have been found to contain either oxide of chromium or oxide of titanium in this soluble state. Among the samples from contiguous beds, this diversity in composition made by the presence of some oxide of chromium or oxide of titanium existed; and while the bulk of a bed of ore was pure, continuations of the bed, or associated ore, yielded notable weights of oxide of chromium or oxide of titanium in the different samples.

The suggestion we would make to the iron master in view of these facts is, the possibility of the quality of the pig metals in anomalous cases being greatly influenced by the admixture of some ore containing the oxides of chromium or titanium, with the basis ore of good quality. This may take place by the main bed being crossed by veins of mixed ore, or by the workings passing into contiguous beds where one kind of ore is used. In other cases, where the iron master can gain the great advantage arising from mixing ores, one of the kinds may contain the contaminating oxides and injure the iron.

We subjoin some results of analyses showing the proportion of oxide of chromium to tho metallic iron contained in the ore: 1st. Magnetic ore—iron, 49; oxide of chromium, 1·40. 2d. Hematite ore—iron, 42·47; oxide of chromium, 1·60. 3d. Brown Massive ore—iron, 64·32: oxide of chromium, 1·90. 4th. Same—iron, 46·70; oxide of chromium, 1·04. More traces have been discovered in some cases, while in other instances a larger proportion of chromium formed an alloy with the iron produced from the ore.—Aug. A. and S. Dana Hayes, Assayers to State of Massachusetts.—*Railway Times.*

MANUFACTURE OF IRON DIRECT FROM THE ORE.—At the Ringgold Iron Company's Works, in Pennsylvania, an improved process of manufacturing wrought-iron, the invention of Mr. J. Jameson, has for some time past been in successful operation. The furnaces are somewhat of an oven-shape, having, however, a stack from the top of about twenty feet in height. A refining fire is in front, into which the blast-pipes enter on the side. The gas that is evolved from the fuel passes into a chamber, where combustion takes place, and thence the combustion of the gases continues till above the fifth chamber it passes (together with such deleterious qualities as have been taken up from the ore in its progress) through and out of the stack. The five chambers are called in the Jameson patents the deoxidizing chambers. The ores are calcined, then crushed, and first placed in the top or fifth chamber. Into the first and second chambers a small jet of steam is injected, whereby hydrogen is generated for the purpose of aiding in desulphurizing and dephosphorizing the ores. The floor of the top chamber is a table made of fire-clay blocks, with an opening at the end opposite from the door or entrance through which the raw ore is thrown in. On this table the ore is spread out, and after being subjected to the operation of the burning gases, it is then pushed down through the opening at the end of the table opposite to the door on to a like table in the chamber below, where it is again spread out, and here it remains for a time and in like manner passes on to the table of the third chamber; there, after undergoing a like operation, it is passed to the second chamber, thence it goes to the bottom or the first chamber. Thus every particle of the ore is equally operated upon. By this time the ore is almost a pulp, and then it is passed into the charcoal bed and refining chamber. Here the loop is soon formed, when it is taken out, and the hammer soon presents you with a bloom of from 225 to 250 lbs. weight. It is well known that the blooms produced by the direct processes are of inferior quality, whilst a very large quantity of ore and fuel is used in their production. With the Jameson process these difficulties are avoided—a ton of blooms being produced with the same quantity of ore and fuel as is now employed to make a ton of pig metal in the blast furnace. The production is stated to be unfailingly uniform.—*Mining Journal.*

CASTING STEEL UNDER HIGH PRESSURE by means of gunpowder, is thus described by the inventor: It is well known that cast steel run into moulds is subject to blister and is otherwise porous, which defect reduces considerably its toughness. In order to give this metal its requisite tenacity it is subsequently re-heated and then rolled or hammered. As many articles, such as cannon, cannot be treated in this manner, I have devised to submit them to a high pressure whilst in a liquid state, enclosed in their same moulds, maintained in iron flasks. For this purpose, immediately after running a cannon, I cover hermetically the head by a metallic cap, by means of bolts or other devices attached to the flask. This cap is fitted in its center with a vertical pipe, and provided with a cock at its lower extremity, whilst its upper extremity is closed by a washer pressed by a bolt in such manner as to act as a safety valve. Before attaching the cap, at, supposing, one inch from the surface of the liquid metal, I introduce in the vertical pipe, and between the cock and the washer, a charge of about one quarter of an ounce of a powder, prepared in the proportions of eighty parts of saltpetre and twenty parts of charcoal. On opening the cock this powder falls on the metal, ignites and engenders about one-third of a cubic foot of gas at 3,000 Fahr. These gases exert on the liquid metal a pressure which is transmitted throughout the entire mass, thereby condensing the same and expelling the blisters. The effect thus produced is equivalent to the pressure of a head of liquid metal ninety feet high, admitting that the capacity between the cap and the surface of the metal contains thirty cubic inches. By making the flasks sufficiently strong, the charges of the powder may be varied, so as to produce by its ignition a uniform and general pressure, which is preferable to the partial, irregular and momentary action of a hammer.

New Blowing Engines for the Wigan Coal and Iron Company.—These engines blow air into ten blast furnaces, through a wrought iron tube seven feet in diameter, the blast being delivered at a pressure of about four pounds to the square inch. Before entering the furnaces, the blast is heated to from 800 to 1,000° Fahr. The furnaces have closed tops, in the usual manner. To each furuace there are four hot blast stoves. The present number of boilers put down is ten, double-flued and ranged in front of the engine house, which is a magnificent structure, with a tower at least 100 feet in height. The machinery is from the works of Messrs. Nasmyth, Wilson & Co., of Manchester. There are three engines, with six blast cylinders, and six high and low pressure steam cylinders. The diameter of the air cylinders is 100 inches; of the high-pressure steam cylinders 45 inches; and of the low-pressure steam cylinders 66 inches. The stroke of each engine is 12 feet. All the steam cylinders have steam jackets; also the exhaust pipes between the high and low pressure cylinders. The engine beams are 36 feet from center to center. Each pair of engines has two blowing cylinders; each blowing cylinder is above each steam cylinder. The engines being worked by high and low pressure, the high cylinder is connected with the low one by two side levers and beams, already referred to. The working apparatus is in duplicate, worked from one end, so that both cylinders are worked by steam valve gear; this valve gear is worked by an entirely new motion, patented by Mr. Robert Wilson. The air to supply the blast is conveyed into the engine house through a tower and an underground tunnel.

Iron and Steel Institute for Great Britain. — At the preliminary meeting of this organization lately held in London, Mr. Isaac L. Bell, of Middleboro', in the chair, it was resolved to ask tho Duke of Devonshire to be the first president, 1st, because Englishmen are very fond of having a nobleman at their head; and, 2d, because the Duke, in addition to having great possessions in mineral property, is at the head of a concern which is amongst the foremost and the most extensive of modern iron and steel works in England.

The following subjects wero suggested as proper for the consideration of the Institute:

Iron Ores.—Details of newly discovered deposits of iron ores; analyses of various English and foreign ores; mode of occurrence; cost of working; probable extent of deposits; distribution of ores; ironstone mining.

Blast Furnaces.—Calciniug kilns; use of furnace gases for calcining; blast furnaces—modes of construction; best proportions of various classes of minerals to be used; engineering arrangements; blowing engines; hoists; utilization of furnace gases and furnace slag; heating stoves; tuyeres; casting arrangements; generation of steam; construction of chimneys.

Conversion of Pig into Wrought Iron.—Improvements to save expense of re-heating pig-iron; improvements in puddling and heating furnaces; fettling; mechanical puddling; simplification of converting processes; methods of arranging forges most effectively; utilization of waste heat from furnaces; selection of materials for different classes of finished iron; mill work; arrangement of different kinds of mills; details of manufacture of rails, plates, bars; special sections; new application of iron.

Foundry Work.—Special qualities of various kinds of pigs; cupolas; improvements in melting furnaces, and in arrangements for moulding with rapidity and certainty; testing iron.

Steel.—Relative merits of various plans for the production of steel; manipulation of cheaper brands of iron for steel making; applications of steel.

Metallurgy.—Solution of numerous disputed points in connection with the metallurgy of iron and steel; verification of Bunsen's and Playfair's experiments; improved methods of practical and expeditious analyses of iron; purification of iron from deleterious elements; further examination of the properties of the alloys of iron; influence of magnetism upon iron and its alloys at various temperatures.

Miscellaneous.—Statistics of the position and development of the iron and steel manufacture in this and other countries; reports on special features of foreign iron-fields and iron and steel works.

Philadelphia and Reading Railroad Company's Rolling Mill. — This mill is eligibly situated about two miles north of the Reading City passenger station, at the point where the East Pennsylvania railroad diverges from the main trunk. The mill-house is 413 feet in length by 93 feet in width, with a spacious wing projecting from one side. There are twelve puddling furnaces, eight heating furnaces and two re-heating furnaces. There are two trains of 23-inch three-high rolls. The finishing train is two-high. The rails rolled are of three weights—64 pounds, 62 pounds and 56 pounds per yard—for use in localities according to character of traffic. The rails contain about one-third part new iron.

The housings and bed-plates of the trains were made by Matthews & Moore, of Philadelphia, and are not only heavy and strong, but very accurately fitted. This accuracy of workmanship, such as characterizes the best marine engineering, is new, but equally important in rolling mills, and is a feature of Matthews & Moore's work to which we have previously referred in speaking of their machinery at the Pennsylvania Steel Works, and at the Abbott Mill in Baltimore. The saw machinery of the Reading mill is by the same builders. The engines are by George W. Snyder, of Pottsville, the work being surpervised by J. E. Wootten, Engineer of Machinery for the P. & R. R.R. Co. All the boilers, castings, furnaces, &c., were made at the company's shops in Readiug. The general plan, and the details of the parts not otherwise specified above, were made by Mr. W. E. C. Coxe, and the whole was erected under his superintendence, and is run under his able management. The carrying out of Mr. Coxe's plans was entrusted to Mr. Samuol Stroh, the present foreman of the mill.

The capacity of the mill was recently tested as follows: During twelve hours, $92\frac{1}{2}$ tons (2,240 lbs.) of rails (405 bars of 64-lb. rails) were produced from eight heating furnaoes; theso were all heated a second time after blooming in two re heating furnaces, giving an average of $46\frac{1}{4}$ tons for each of the latter. The product of the mill in January was 1,437 tons of finished rails.

GALVANISING IRON.—DRAWING OFF THE OFFENSIVE VAPORS.—The application of zinc with tin as a coating for iron, has become a most important manufacture in and about Birmingham. The application of iron for every purpose of construction is practically only limited by the difficulty of preserving the surface from rust. No method has yet been adopted which is at once so cheap, so effectual, and so enduring as galvanizing, and the works in which that process is carried on have very rapidly increased. To galvanise iron it is immersed for a certain period in an acid to cleanse the surface, after which it is dipped into a bath containing zinc and tin melted. In this salts of ammonia are thrown, which operates on the metal as a solvent, and enables it to be more evenly distributed over the surface. From this bath is given off a dense, pungent, white-colored vapor, which is heavy, and, especially in damp weather, spreads and becomes offensive. Complaints have been made of these vapors, and various plans have been adopted for the purpose of preventing them from passing into the atmosphere, but heretofore without success. The Wolverhampton Corrugated Iron Company have adopted a plan which is found very effectual. The top of the bath is surrounded by a flue which forms a projecting lip, and from this run one or more iron pipes communicating with a powerful fan. From the fan a large flue extends to an annealing furnace. The fan, by creating a vacuum in the pipes, causes a strong current of air to pass over the surface of the bath, which drives the vapor into the furnace, where it is entirely consumed. Experiments are in progress to condense the vapors so as to utilize them, instead of consuming them in fires.

CLEVELAND ROLLING MILL.—The works of this company were first established in 1857 for the manufacture of railway and merchants' bar-iron, since which time their capacity has been constantly increased. In 1859 the first blast furnace was built; afterwards, in 1864, the mill of the Railroad Iron Mill Company was bought and furnished with new machinery, and a second blast furnace erected. The two furnaces are now making from 45 to 50 tons per day, and the two rail mills have a capacity of 35,000 tons of rail per annum. The bar iron mill is capable of making from 12,000 to 14,000 tons per year. The company commenced the manufacture of Bessemer steel in September, 1868, with one five-ton converter, and are at present turning out some fifteen tons per day. They are now putting up another five-ton converter and erecting reverberatory furnaces and cupolas, which will enable them to increase the capacity of steel production from 40 to 50 tons per day. The greater portion of the steel has been made into rails, which have thus far shown the best results. The Bessemer steel made by this company has been very even in quality. The works are situated near the best iron-producing region of the country—the Lake Superior region—the ores of which are remarkably well adapted for producing steel by the Bessemer process. Besides turning out steel and iron rails of good quality, they manufacture beams, girders, merchants' bar, boiler rivets, fish plates, spikes, nuts, bolts and a variety of other articles used in railway construction and repairs. The works are favorably situated, having water and rail connections with the whole west and northwest.—*American Railway Times.*

FIBRE OF WROUGHT IRON.—In a paper read before the Liverpool Polytechnic Society, "On the Structure of Metals," Mr. Vivian stated that the "fibre" or "silky lustre" exhibited in the fracture of good iron is only the effect of the light reflected from inner surfaces of myriads of minute cells exposed by the fracture, that the form of these in their normal state is spherical, or nearly so, but they become changed in the process of rolling, &c. Air has no access to these cells in their concealed state, but when they are exposed to the action of the atmosphere they soon become tarnished. The cellular construction is not an accidental occurrence, but it is the proper constitution of the metal, and appears to take place under the combined effects of heat, the repellent force, and the coherent force inherent in the substance. The mechanical properties of tenacity, ductility, &c., must greatly depend on the perfection of the cell system, and as much importance should be attached to this as to the degree of chemical purity necessary to insure a good iron, since it is well known that from iron of the same chemical purity various qualities of metal may be produced by working at an improper temperature, or by cooling too suddenly.

PLANT AND OPERATIONS AT FIRTHS' STEEL WORKS.—Dr. Percy thus refers to the works of Messrs. Firth & Sons, of Sheffield, in a letter to the London "Times:" For casting large ingots each crucible contained about 50 lb. of molten steel. At a given signal the pouring of the metal commenced, and in sixteen minutes the ingot mould had received the contents of the 212 crucibles. There was no bustle or confusion. The men, 200 in number, knew their drill, and did their duty without a hitch. The ingot weighed 86 cwt., and was designed for the steel tube of an Armstrong gun. The receptacle employed by Krupp for receiving the steel from the crucibles, in the first instance, was dispensed with; but that is only a point of minor detail. The Messrs. Firth have cast nine-ton and sixteen-ton ingots. A nine-ton ingot is required for the 23-ton Armstrong gun. Messrs. Firth have expended about £30,000 in the erection of two 25-ton Nasymth hammers, re-heating furnaces, on Siemens' principle, and other appliances. The anvil block of each hammer is cast iron, cast in one piece, and weighs 164 tons. The length of hammer stroke is nine feet six inches.

THE SIEMENS FURNACE is being somewhat extensively applied for puddling, and so far as has been reported, with good results, there being not only a saving of fuel, but a very considerable saving of iron, while also the balls, especially if fettled in rich ore, are of better quality. The importance of the highest quality of fettling material is very great where the iron to be puddled is largely charged with phosphorus. Some of the Cleveland ironmasters puddling highly phosphuretted pig, import large quantities of a very pure ore from Norway and Sweden, and these, used as fettling, not only add a large quantity of iron to the charge, but they take up a large proportion of phosphorus or phosphoric acid in the slag; and the puddled bar, which would otherwise be very cold short, is found to be fine grained, ductile, and fitted for nearly all the purposes of good makes of bar iron.

STEEL RAILS AND TYRES.—Messrs. William Bird & Co. in their monthly circular speak as follows of the relative use of steel for tyres and rails in England and on the Continent. They say: "Compared with foreign railway specifications for 5,000, 6,000 and 8,000 tons of rails, and 5,000 to 8,000 and 10,000 Bessemer steel wagon tyres on a line, our home requirements of a few tons at a time (Bessemer steel rails in the proportion of 200 tons to 5,000 tons of wrought iron are just now advertised by the Great Northern) appear quite insignificant, and in the course of the past year there have been contracts of 40,000 tons given out to French works for both Bessemer and Martin rails, and 5,000 tons of French make have even found their way to the United States lines."

Machine Puddling.—In this direction nothing appears to have been done since the unsuccessful attempts made at Dowlais, and those, still earlier, by Mr. Tooth and Mr. Yates. Nor do we learn that the revival of a former attempt to introduce air directly within the iron in the puddling furnace, by means of a tubular rabble with a flexible air pipe, has made any progress. This mode of introducing air was heard of some little time ago, as "the Richardson process." So, too, there was "a Radcliff process" of knocking four or five puddled balls into one, and rolling or forging them direct into a single large bar. There were obvious objections to this mode of working, that especially of the risk of unsound welds, and the saving of a single heat is not enough to compensate for this risk, so fatal to the product.—*Engineering.*

Tempering Taps.—A correspondent of the "Scientific American" writes as follows: Most of your readers are aware of the difficulty in tempering taps and reamers without springing, especially long and large ones. To accomplish this let the blacksmith select his steel for the job and forge the tap with a little more than the usual allowance, being careful not to heat too hot, nor to hammer too cold. After the tap or reamer is forged, heat it and hold it on one end upon the anvil. If a large one, hit it with the sledge; if a small one, the hammer will do. During this operation the tap will give way on its weakest side and become bent. Do not attempt to straighten it. On finishing and hardening the tap will become perfectly straight. If any are doubtful, a simple trial will convince them.

Atlas Works, Bessemer Plant, Glasgow.—These works are fully illustrated in "Engineering," Jan. 1. A pair of three-ton vessels are arranged in the ordinary English style. There are two air furnaces and two cupolas, capable of holding the whole charge; also two spiegel furnaces. The charges are elevated by hydraulic hoists. There are two independent pairs of blowing cylinders, with twenty-inch steam and 2 6-inch air cylinders of two and one half ft. stroke, making seventy revolutions. The converters have cast-iron trunnion hoops. There is nothing new in the design. The American works have greater facilities, and can produce a larger product with the same number of vessels.

The Richardson Process of Puddling.—This is reported to be gradually maturing in England, and several improvements are announced. The blowing out of the silicon sparks through the stopper-hole has now been overcome by the employment of a hooded rabble. It is said that at the Parkhead Works, near Glasgow, where the process has been in operation nearly a year, not a bad bar has been produced. At Messrs. Palmer's Works, Jarrow, the use of the tubular rabble has been supplanted, Mr. Ridley having introduced a method of injecting the blast through the pipes introduced through openings at the side of the furnace, and excellent results are said to be produced by this method.

Fire-brick in Steel Making.—An exchange states that many works are erecting in this county for the manufacture of steel rails, and that one of the steel furnaces will use a million fire-bricks a year! This can hardly refer to the Bessemer Works, where no fire-brick are used, except to line the nose of the converter, and for the spiegel furnace, which will last a couple of years. The Siemens furnaces are probably as durable as ordinary reverberatory furnaces, and we can hardly imagine a steel process in which brick alone will cost say ten dollars per ton of product.

Steel Railway Carriages.—The recent report of the Oude and Rohilkund Railway Company, states that the steel rolling stock, which had been the cause of some anxiety to the board, was very likely to turn out a complete success. They had, at present, two long metal carriages, capable of accommodating 200 passengers each, and were found to be very suitable for the traffic. The remainder of the steel rolling stock, for which a supply of wheels and axles had been forwarded, was now being made available.

Improved Rolling Mill Machinery.—Messrs. Thomas Perry & Son, of the Highfields Works, Bilston, have made a train of 24in. rolls, three high, for rolling steel rails. They have also just completed a universal mill for rolling long narrow plates without shearing. This kind of rolling is effected by the addition of vertical rolls behind those which are horizontal, and it is a plan which has been for some time most successfully worked on the Continent. (See article on universal mill, in another column.)

Washing Coal.—Since the expiration of the patent for the French coal-washing machine, so long held by Mr. Morrison, of Ferry-hill, it is coming into extensive use, and with the best results. Worthless "slack" is now powdered, its pyrites separated, and it is afterwards coked into excellent fuel at an almost insignificant cost. In France and Belgium great attention is paid to washing refuse coal, and the adoption of the French mode would save vast sums of money here.

Troy Bessemer Steel Works.—The steel works of Messrs. John A. Griswold & Co., burned in October, are being rebuilt by Mr. A. L. Holley, late superintendent of the Pennsylvania Steel Works. The two-ton converter has been at work all winter, producing some ten tons of ingots daily. The five ton plant will be considerably enlarged, and will be running in July. A new blowing engine, the largest Bessemer engine in this country, is building by Messrs. Paulding, Kemble & Co., Cold Spring.

Remarkable Production of a Charcoal Furnace.—From January 1st to 31st inclusive, the Irondale furnace of E. Harrison & Co., produced 784 tons of pig-iron of 2,268 lbs. to the ton. The daily average was therefore $25\frac{1}{3}$ tons. This is a charcoal furnace measuring $9\frac{1}{2}$ feet in the bosh, and 40 feet in height, and uses nine-tenths Iron Mountain ore.—*Bulletin of the Am. Iron and Steel Association.*

The Specific Gravity of Steel oscillates between 7.2 and 7.9. The hardening of the metal by tempering is accompanied, as Réaumur long ago observed, by a notable diminution of specific gravity; and M. Caron has noted that the specific gravity of steel diminishes with the number of times it is tempered.

New Furnace of the Sterling Iron and Railway Company.—A new blast furnace building for this company, after the designs of Mr. Rumpff, of the West Point Foundry, is 60 feet high, with 12 feet boshes.

Large Rolls.—A pair of rolls for Sir John Brown's Works, Sheffield, recently cast at the Phœnix Works, Bilston, were of the following dimensions:—Length of roll $15\frac{1}{4}$ feet, diameter 3 feet; weight, 18 tons.

Highest Blast Furnace in the United States.—The Port Henry furnace, 70 feet high, with 16 feet bosh, is stated to be the highest American furnace.

RAILWAY NOTES.

RATE OF PROGRESS OF THE MOUNT CENIS TUNNEL.—During the past year an advancement of 1,320.15 meters has been made at the Mount Cenis tunnel, of which 638.60 was driven on the Italian side, and 681.55 meters on the French. The advancement has been 110 meters per month, or 53.20 on the Italian side, and 56.80 on the French; and at this rate of progress the time necessary for the completion of the tunnel would be twenty-eight months, or about April, 1871, and for opening the railway about six months more, or in less than three years.

The following table, from "Engineering," shows the yearly progress that has been made with these works since their commencement in 1857:

Year.	Bardonnêche.	Modane.	Total Advancement. Each Year.	Total Advancement. At end of Year.	Expenditure.
	meters.	meters.	meters.	meters.	francs.
1857. 1858.	284.85	212.75	497.60	497.60	3,369,000
1859.	236.35	132.75	369.10	866.70	1,630,000
1860.	203.80	139.50	343.30	1,210.00	3,000,000
1861.	170.00	193.00	363.00	1,573.00	2,500,000
1862.	380.00	243.00	623.00	2,196.00	2,000,000
1863.	426.00	376.00	802.00	2,998.00	3,500,000
1864.	621.20	466.65	1,087.85	4,085 85	6,552,000
1865.	765.30	458.40	1,223.70	5,309.55	5,502,000
1866.	812.70	212.29	1,024.99	6,334.54	5,644,000
1867.	824.30	687.81	1,512.11	7,846.65	6,000,000
1868.	638.60	681.55	1,320.15	9,166.80	7,500,000
	5,363.10	3,803.70	9,166.80	....	47,197,000

ENGINES, WORKING AND EXPENSES ON THE SEMMERING RAILWAY.—At a recent meeting of the *Société des Ingénieurs Civils*, M. Gottschalk, locomotive engineer of the South Austrian Railway system, stated that the successive improvements in traction on these lines, and especially on the Semmering section, up to the end of 1865, had not only been maintained, but had still continued to progress in 1867. Passing over the results of 1866, which were abnormal in consequence of the war, the expenditure on the entire system, Semmering included, had been 0.977f. per train kilometer, as against 0.992f. for 1865. For Semmering alone the cost of traction in 1865 had been, for those trains that could be taken up entire, 1.70f. per train kilometer, and for goods trains divided and taken up at two trips, 3.40f. In 1867 these figures were reduced to 1.666f. for the single train, and 3.33f. for the double train. These reductions would have been greater but for the work to replace in proper condition the overworked rolling stock of the year of the war, and the unusual quantity of snow during December. It may then be affirmed that the already so greatly reduced expenses of traction on the Semmering and other lines are not, as some persons think, the consequences of its recent construction. Locomotives in use last above eighteen years; their repairs are placed to the current account, as well those of vehicles of all kinds. Damage to rolling stock, often considerablo, caused by foreign service, is always borne by the traction service. The radius of 189 meters in the Semmering curves prevents the use of two locomotives to the train without danger, but this obstaclo does not exist on the Brenner line, and the company has been authorized to run its trains of 350 tons across in one journey by means of two locomotives, one in front and the other in rear of the train. Besides complete security in case of any breakage in the coupling, this plan offers obvious advantages, which it is unnecessary to specify. One great difficulty in working the Brenner line is the means of regulating the speed in the descent. The proportion of brakes sufficient on the Semmering with curves of 189 meters is not so on the Brenner with curves of 300 meters, although the inclines are the same on both lines. The Semmering line is double, the Brenner single; the consequence is a marked difference in adhesion. These difficulties are to some extent overcome by the use of sand, but though it is largely employed it is insufficient. The descent was therefore an occasion for the use of reverse steam, for which purpose all the Brenner locomotives have been provided with the Le Chatelier apparatus, similar to that adapted to the Mediterranean locomotives.

The new goods engines, on the same general principles as the modified ones of the Semmering, with the entire mechanism and exterior appurtenances, give the best results. The maximum weight of the goods trains last winter reached 369 tons. Here the gross weight of each train became

Weight of wagons	369 tons.	
" 2 locomotives—94,600 kilos..	131	"
" 2 tenders—36,400 kilos......		
	500	

Multiplying this weight by 6 + 25 kilos. we find that the tractive power developed is 155,000 kilos., and that the work of these two engines at a speed of 15 kilos. por hour is about 850-horse power, or 425-horse power per engine. Under these circumstances vaporization is not forced, as each square meter of heating surface only equals two and a half horses.

RAILWAY PROGRESS IN RUSSIA.—The first railway in the empire was opened in 1838, and for seven years it was the only one. One or two short lines were opened in the course of the next two years, but, in 1848, a line was opened from Warsaw to the Austrian frontier. It was not until after the death of the Emperor Nicholas that railway enterprise made any very great strides in Russia. Since then, however, the process has gone on upon an accelerating scale. There are at present 5,960 versts of line open, 3,337 versts are in courso of construction, and a Council of Ministers has decreed concession for eight new lines, declared to be indispensable, the gross length of which is 3,235 versts. Tho majority of tho lines opened have been constructed with foreign capital, and the funds for the new undertakings are sought for from the same source, and there is now a full stream of English capital directed from home projects flowing into Russia to enrich that country, and to increase the strategic power of the Czar.

The following are the lines in course of construction: Kiev-Balta (all that remains to be completed of the Moscow-Odessa line), 428 versts; Odnoga-Berdcyzeff, 27 versts; Odnoga-Woloczysk (Polesia-Bukowina), 167 versts; Tiraspol-Kischeneff (Bessarabia), 65 versts; Kursk-Charkoff-Taganrog-Rostoff (Moscow and Taganrog line), 763 versts; Jeletz-Orel (continuation of Grias-Jeletz), 173 versts; Orel-Witepesk (last portion of the line connecting the St. Petersburg-Warsaw and St. Petersburg-Moscow-Odessa lines, open to Rostavl, four-fifths of the distance), 493 versts; Grias-Boryssogleb (extension of the South-Eastern in the direction of the Volga), 192 versts; Kaslov-Tambov (extension of the South-Eastern in the direction of the Volga), 74 versts; Odnoga-Schuya, 84 versts; Troizka-Yaroslav, 196 versts; Poti-Tiflis, 284 vorsts; Moscow-Smolensk (direct connection between Moscow and the Riga-

Dünaberg-Orel line), 391 versts. Total, 3,337. Of the Russian lines fifteen have a government guarantee, and their capital amounts to 237,856,000 roubles.

Few of the Russian railways have, as yet, managed to become self-supporting, and Englishmen are warned by newspaper correspondents to keep clear of the railway mania, now at its height. The government is understood to have suffered some heavy losses on account of its guarantees, but it can afford to stand many more, if necessary to the development of the country.

Differing from the standard adopted in most European countries, the Russian gauge is five feet, an arrangement intended to prevent foreign railway carriages from entering the country in peace, and still more in war. Only in Poland the ordinary German guage of four feet eight inches has been adhered to. A weak side of the Russian railways is the insufficiency of their rolling stock, which, being almost entirely imported from abroad, is a dear commodity, and, in consequence, kept at a low figuro. Accidents are not very common, Russian engine-drivers, who are apt to indulge their liquorous propensities, being discarded on many lines in favor of steady Germans. Yet, as the number of passengers is small, the death-rate by accident is necessarily great. *From Correspondence of the London Times.*

Effect of Northern, East and West Lines upon New York City.—This subject is discussed at length in "Harpers' Magazine;" the conclusions are as follows: Upon the completion of the Hoosac tunnel, Boston will have two lines direct to the lakes. The line by way of Springfield encounters an elevation of 1,450 feet above tide, and, in its ascent towards the west, has a grade of 83 feet to the mile. The line by way of the tunnel rises at the summit to 1,106 feet, and passes through the tunnel at an elevation of 838 feet above tide; but it has no grades steeper than 58 feet.

New York enjoys the benefit of tide-water from Troy to the ocean, and of a railway whose steepest grades (at Poughkeepsie) are only fifteen feet. The Harlem road is less favorably situated for carrying through freights, as it is obliged to pass over the same mountain range through which the Hudson River makes a clean sweep. Except for about 104 days in each year, when the river is closed with ice, New York has the immense advantage of the Hudson river, capable of floating the largest barges at rates for freight with which railroad lines cannot compete, and at all times it has two lines of railway. In extending her enterprises to Lake Ontario, it will be impossible for Massachusetts to secure the advantage which the New York Central enjoys in passing through the Allegany at the dip at Little Falls. The road and canal there are about 300 feet lower than Lake Erie, and but about 100 higher than Lake Ontario, whereas the line suggested for competition must pass over the mountain at unfavorable grades.

New York has the inestimable advantage of a canal and line of railroad which *descend* from Lake Erie to tide-water, with the exception of a trifling counter-elevation, and has only 110 feet to overcome between tide-water and Canada. If New York had no road but the Erie it would be on a footing with the Atlantic sea-ports south, as its grades are about on a par with those encountered by them. Pennsylvania, Maryland and Virginia are obliged to surmount elevations in the neighborhood of about 1,500 feet. North and South Carolina have high and nearly impassable mountains behind them; but South Carolina avoids hers by using the roads of Georgia, which are constructed around them and through an opening at Chattanooga in another range. The history of the Erie railroad will be relied upon by many to prove that it was a great error in policy not to confine ourselves to *the route indicated by nature* for our canal and great lines of railway. Washington was the first to point it out when in command of the revolutionary forces located in the valley of the Mohawk, and the first to express the hope that it would be improved. His education as an engineer enabled him at a glance to perceive that New York stood unrivaled in her facilities for intercourse by land and sea, and consequently for commercial supremacy.

Italian Railways and Works.—The public attention is so much directed to tho Mont Cenis tunnel that the works upon subordinate portions of the great line connecting the northern and southern sides of the Alps are little noticed. Upon the Italian side of the mountains there is much difficult engineering. The line from Bardonnèche and Bussoleno, 25 miles long, has a tunnel three-fourths of a mile long, and several fine bridges at Meana, a succession of lesser bridges on the whole line, and no less than 24 tunnels in all. A line 40 miles long from Gloia and Tarente has many features of great difficulty, requiring "trial sections" and careful preliminary reconnoissances before any attempt could be made to delineate the approximate route. An iron bridge over the torrent San Stephano, has a central span of 180 feet, and is 200 feet above the water. A viaduct over the Castellanela is 240 feet high from the river. This is an iron structure on lattice-work iron piers. The character of the structures on these lines is highly spoken of by experts.

The Italian railways in operation at the close of last year was as follows:

		Kilom.
Alta Italia Railway Company:		
	Piedmontese lines	1,030
	Lombard lines	477
	Central Italian lines	294
	Venetian lines	437
	Total	2,238
Roman Railway Company:		
South section	Naples and Leri, Cancello and St. Severino Railway	181
South section	Ancona and Orte Railway	238
North section	Leghorn, Azetina and Ligurian lines	761
North section	Empoli, Siena and Orvieto Railway	216
	Total	1,396
Southern Railway Company:		
	Mediterranian network	183
	Adriatic network	984
	Voghera, Pavia and Brescia Railway Company	149
	Total	1,316
Victor Emmanuel Railway Company:		
	Palermo and Termini Railway	37
	Messina and Catania Railway	95
	Reggio and Lazzaro Railway	17
	Total	149
Total of four groups		5,099
Turin and Cirie Railway		8
Fell Railway over Mont Cenis from Susa to Frontier		27
	Total	5,134

A New Engineering Feat is talked of at Chicago. It is proposed to cut off the river several miles above the city, and conduct its entire volume of water to the lake by a canal, and convert the channel into a system of railroads, where all the lines converging in the city might meet in one grand central station.

THE CORNWALL BRIDGE.—The bill passed in the State Assembly for the construction of a suspension bridge across the Hudson river, 42 miles above New York city, appears likely to be acted upon, and the designs and calcu ations for the structure are now almost completed. The total length of the bridge, including approaches, will be 2,499 feet, the length between towers, 1,665 feet; the clear span, 1,600 feet; the height of the towers, 280 feet; distance from platform to water level, 150 feet. One of the towers will be in 30 feet of water, the other will be a land pier. The bridge will be carried by twenty cables disposed in four systems; each cable will be fourteen inches in diameter, formed of steel strands, disposed as in Mr. Roebling's bridge at Cincinnati. (It is now proposed to make the cable of steel bars.—Ed. V. N. Eng. Mag.) Thero will be 58,084 cubic yards of masonry in the tower.

There will be a road platform as well as a railroad track, which latter is calculated to a working load of 2,400 tons. The platform of the bridge would be filled by 32 passenger cars, or 53 locomotives, and 18,000 people, whilst the working strength allows for the crowding of 34,560 people and 60 locomotives upon the platforms at one time.

The bridge, which is estimated to cost about £500,000, will connect the mining districts of Pennsylvania with the New England States, and effect a saving of four shillings a ton on the 4,000,000 of tons of coal now consumed annually in New England. At present about 1,000,000 tons are carried every year down the Hudson to the depots along the coast. By means of a short branch made to the bridge, the Erie railway will be enabled to obtain a station in New York, and be saved the expense and inconvenience of transferring passengers and goods by ferry to their terminal station in Jersey City.

Pending the completion of the bridge, a ferry will be established at the point of crossing, for transfer of the traffic, as the railway will be completed up to the east and west banks of the Hudson long before the permanent connection can be made.—*Engineering.*

WOODEN MINING RAILWAYS.—The wooden railroad now completed between Clifton and the Adirondack mines in New York, is described as folows: The rails are of hard maple scantling, 4 x 6 inches, set on edge in slots in round ties, and keyed in the slots by two wooden wedges driven against each other, project two inches above the ties. The rails admit the bending sufficiently to make the curves.—The ties are laid on the earth and ballasted in the usual manner to two inches of the bottom of the rail. It takes 21,120 feet, board measure, of scantling for a mile, and 1,760 ties at three feet apart. The road is a very rough one, with a great deal of trestle work, some of it over 30 feet high, which is vastly more expensive than a level route. The engines used weigh from ten to fourteen tons. The rails will probably last about five or six years. An engine will move about 30 tons of freight at about six to eight miles an hour, with heavy grades and sharp curves. The company expects to move over the road next year from 50,000 to 1,000,000 tons freight. Trains have passed over the road, light, at tho rate of twenty miles an hour; but this would not do for freight.

The proposition to build a wooden track railway along the Lake Superior copper range from Portage Lake to the Cliff mine has met with great public favor. The cost, except the first five miles to gain the summit of the range, has been estimated (wooden track) at $4,000 per mile; the bidding price for timber prepared and delivered being $2,300 per mile, leaving $1,700 per mile for construction account. This is considered more than sufficient, as all agree the labor will be no greater than that of making a common wagon road or earth-covered corduroy, which is done generally for about $4 or $5 per rod, or $1,250 to $1,600 per mile.

THE FIRST EFFECTIVE LOCOMOTIVE IN AMERICA.—The first effective locomotive engine in America—the "Old Ironsides"—says Mr. E. Haskill, in the "Coachmakers' Journal," was buil in Philadelphia, from a draft by Rufus Tyler, a brother-in-law and partner of the late Matthias Baldwin. In consequence of a misunderstanding the copartnership was dissolved, and Mr. Baldwin completed the engino in 1832. The wheels were made of wood, with broad rims and thick tires, the flange being bolted on the side. The engine was first put in motion on the Germantown and Norristown railroad. She ran a mile an hour, and was considered the wonder of the day. On trial it was ascertained that the wheels were too light to draw tho tender, and to overcome this difficulty the tender was placed in front of the engine, which kept the wheels on the track. Mr. Baldwin and his assistants pushed the engine ahead until it attained some speed, when they all jumped on, their weight keeping the wheels from slipping. The boiler being too small for tho engine, steam was only generated fast enough to keep the engine in motion a short time, so that they were compelled to alternately push and ride until they arrived at the Germantown depot. The return trip to Philadelpnia was performed by alternately riding and pushing in the same manner.

Several successive trials were had during the year following; after each, Mr. Baldwin added improvements and made alterations in its mechanism. That same engino is still in existence in Vermont.

RAILROAD MATTERS IN CALIFORNIA.—The open winter has been favorable to railroad enterprises on the Pacific slope. The Central Pacific has been enabled to push forward supplies, and to continue grading and track-laying without interruption. The new mineral discoveries in Nevada will much increase the traffic on this road through California and Nevada; indeed, the way business generally on both ends of the Pacific railroad has exceeded all expections for so early a period.

There are some signs of activity on the Western Pacific railroad, from Sacramento to Oakland. Meanwhile the California Pacific, via Vallejo, has reached Sacramento, and the passenger traffic is steadily increasing. The connection with the Nepa Valley railroad is progressing. The extension to Marysville is expected to be completed by the middle of summer. Marysville will soon have railway connection with Sacramento on the east side of the Valley, through the Central and Yuba lines.

The Southern Pacific railroad is graded from San Jose to Gilroy, and some 30 miles of track nearly completed.

BALTIMORE UNION RAILROAD.—This enterprise was started some time since, with a view of giving an outlet at tide-water to the various railroads, built and contemplated, entering the city on its north side. It is likely to be fully completed during the ensuing two years. The contractors are, it is said, pushing it forward as rapidly as prudence will allow, and the road will have a tunnel just out of the city some 2,900 feet long. Three shafts have been sunk, but the difficulty of water is so great that the question of making an open cutting to be afterwards arched and filled in is being discussed.

SPANISH RAILWAYS.—The entire railway system in Spain is, in length, about 3,125 English miles, and about £60,450,000 have been expended, without in the aggregato ever having a farthing for distribution as profit. The railways were built extravagantly, they are ill fed for want of good carriage roads in the country, and altogether they are perhaps the most abject failures ever witnessed.—*Bulleonis.*

Stockholm Junction Railway—Engineering Difficulties.—The railway termini of this city have heretofore been at its extreme opposite ends. The new junction line commences at the southern end by entering a tunnel bored through solid granite, and describing a slight curve on plan. This tunnel is 1,500 feet long and 32 feet wide by a height of 19 feet, and passes under a very populous part of the city. Then follows a cutting 2,400 feet long, the retaining walls on either side being 30 feet high, executed in solid masonry. Next comes a bridge across the Söder, after which the line traverses the 'Stad' quarter, then crosses the Riddaneholm canal, and lastly joins the Northern railway over a high embankment. Considering the short distance, perhaps no line in the world has presented greater difficulties to the engineer, and it is only in Sweden that this could have been effected at so low a cost, namely, about £61,000. The granite in the tunnel was blasted by means of nitro-glycerine, 30,000 pounds being used in the operation.

French Railways.—The entire extent of railway in operation in France, Stptember 30, 1868, was 9,934 miles as compared with 9,671 miles September 30, 1867, showing an increase of 263 miles.—The entire amount earned on all the French railways to September 30 this year, was £19,684,405, as compared with £19,424,998 in the corresponding nine months of 1867, showing an increase of £259,407 this year. This increase was entirely attributable to the new network and the miscellaneous lines, the old network presenting a decrease in the first nine months of this year of £188,156. The general result of the working of the French lines of the first three-quarters of this year was a decrease of 4.78 per cent per mile worked, as compared with the corresponding period of 1867; but a somewhat better result may be anticipated for the last quarter of the year. Nevertheless, French railway traffic has shown less elasticity in 1868 than in several preceding years.—*Herapath's Railway Journal.*

The Gauge Question.—The narrow gauge is now replacing the broad gauge system on several of the branches of the Great Western railway. This change will doubtless lead to some legal difficulties, certain coal merchants having built a number of broad gauge trucks, and made contracts with the company for the conveyance of coals therein for a period of several years. It is understood that orders have been received at the workshops of the Delaware, Lackawanna and Western railroad, in Scranton, to rebuild no more locomotives for the wide gauge.—This looks to the not distant laying of the third rail, which is also necessitated by the leasing of the Morris and Essex railroad.

British Railway Mileage Receipts and Expenses.—The earnings of British railways per mile worked have shown a steady tendency to increase upon the whole. In 1849 the total receipts per mile were £1,957; in 1850, £1,994; in 1851, £2,176; in 1852, £2,141; in 1853, £2,345; in 1854, £2,510; in 1855, £2,580; in 1856, 2,660; in 1857, £2,559; in 1858, £2,510; in 1859, £2,574; in 1860, £2,661; in 1861, 2,629; in 1862, £2,522; in 1863, £2,528; in 1864, £2,667; in 1865, £2,700; in 1866, £2,755; in 1867, £2,770. But while the working expenses of British railways were 46.83 per cent of the traffic receipts in 1849, they had increased to 54.57 per cent of the receipts in 1867.

Traffic of the Metropolitan Railway.—It is officially stated that during the six days of the Christmas holidays, from the 24th to the 30th, 800,072 passengers passed along the lines of this company.

A Railway Library of 1,000 volumes has been established by the Boston and Albany railroad. An apartment in the passenger station at Boston has been fitted up for it. The library is divided into two departments, the Consulting and the Circulating.—The first comprises railway enactments, English and American; encyclopedias. The circulating department embraces standard works of interest, instruction, fiction, and bound volumes of the most valuable periodicals of past years, 500 or 600 in number. Any person in the service of the company on the line between Boston and Albany is privileged to take books from this department, two at a time, and to hold them two weeks, the train baggage-masters and station agents along the route transmitting them on Tuesday and Thursday of each week.

The Twelve Great Railway Companies of Great Britain are: The Caledonian; Great Eastern; Great Northern; Great Western; Lancashire and Yorkshire; London and Northwestern; London and Southwestern; London, Brighton and South Coast; Manchester, Sheffield and Lincolnshire; Midland; Northeastern, and Southeastern. The twelve lines own 6,595 locomotives, valued at over eighty millions of dollars.

Warming Street Cars.—The cars of the Albany and West Troy railroad (seven mile route) are warmed by stoves. The stove occupies the place of one passenger (or what would be appropriated to say three passengers in New York city); it rests on the bottom of the car and passes through the seat. The adjacent passengers are protected by high screens.

Large Locomotives.—The 4-cylinder goods engines on the Northern railway of France weigh 59 tons, and have $17\frac{1}{3}$ in. cylinders, $17\frac{1}{3}$ in. stroke, and 12 coupled wheels 3 ft. 6 in. in diameter. The "Pennsylvania," on the Reading railway, has 2 cylinders 20 in. in diameter, 26 in. stroke, and 12 driving wheels 3 ft. 11 in. in diameter. Some of the Great Northern (England) engines weigh 56 tons.

New Line from Europe to India.—The railway just commenced from Constantinople to Adrianople, will ultimately join the Austrian lines at Belgrade, and complete the European part of the Euphrates Valley line to India. This accomplished, its prolongation either along the Euphrates Valley or that of the Tigris can be but a question of time and policy.

Another Trans-Continental Railway.—It is stated that the Czar of Russia has sent two engineers to inspect the Pacific railroad, with a view to utilizing whatever information they may obtain in the construction of a road from St. Petersburg to Chinese Tartary.

The Railway Mania.—A period of remarkable activity in railway construction is just commencing. Cannot promoters and managers be persuaded to avoid the grand mistake of former times—*bad work,* costly to maintain, unsafe, and ruinous in the end.

Locomotive Cars.—"The Engineer" states that arrangements are being made for working a section of one of the largest railway systems in England on the steam carriage principle.

The Bridge at Columbia.—The Pennsylvania railroad bridge spanning the Susquehanna at Columbia was opened to general travel on January 4.

NEW BOOKS.

A Handy Book for the Calculation of Strains in Girders and Similar Structures and Their Strength, consisting of formulæ and corresponding diagrams, with numerous details for practical applications, &c. By William Humber, Assoc. Inst. C. E. Author of a practical treatise on cast and wrought iron bridge construction, a Record of the Progress of Modern Engineering, &c. 12mo. with three plates and nearly 100 wood cuts.

Mr. Van Nostrand is photographing the plates and text of this work and will issue it in a few days.

The "Builder" speaks of the work as follows: This volume is not intended to supersede larger and more elaborate treatises. It is intended to take a place midway between these and the "Engineer's Pocket-book" class. The former are too elaborate for convenient use, the latter have not space enough for the introduction of many useful formulæ. The "Handy Book" represents the mean between the two extremes, and will be found a valuable companion by the practical man. The author not only gives the most applicable formulæ for particular cases, but he illustrates them by means of excellent diagrams, and thus makes his subject easily intelligible to any one whose mathematical knowledge extends to equations. The method of drawing a parabola—the base and height being stated—which Mr. Humber gives, is a happy one. The book indeed recommends itself better than any notice we could write.

The Indicator Diagram Practically Considered. By N. P. Burgh, Engineer. London: E. & F. N. Spon, 1869.

This is a 12 mo. of 160 pages, containing numerous wood-cuts. The object aimed at is best stated in the words of the preface. "The means I adopted" to professionally test some indicator diagrams "were to consider, first, the proportions of the details that regulated the admission, expansion and exhaustion, of steam; and, secondly, their geometrical delineation. Having proceeded thus far, I then concluded that, as the length of the motion for the indicator barrel was virtually that of the stroke of the piston, the scale of the geometrical test that I employed must be subject to that circumstance. I accordingly made a drawing of the cylinder ports, slide valve, link motion, eccentrics and rods, a portion of the length of the piston, length of the connection rod and crank circle at the same scale that the stroke of the piston, in inches, was equal to the length of the indicator diagram. I acquired thus a correct knowledge of the positions of all the details that regulated the steam at the points of admission, cut-off, expansion, exhaustion, compression and lead, in relation to the positions of the piston and crank pin at the same scale as at the diagram; and by laying it on the crank pin's circle, I saw at once *how it was formed in relation to time and speed*, and the *cause of the defects*, if any existed—indeed being the only method of gaining that information *truthfully*, which is illustrated by the plate in the frontispiece."

The work also treats of the indicator and diagrams in all their points and relations.

Long and Short Span Railway and Highway Bridges. By J. A. Roebling, C. E.

Mr. Van Nostrand is producing this work in superb style. It is a large folio, eighteen by twelve inches, with folding plates; some of them 60 inches long, engraved on copper. It will be ready in April.

Mr. Roebling's name, alone, will insure a large sale for this work. The results of his labors and studies, all these many years of devotion to the subjects of iron, steel and bridges, will be eagerly sought for by the profession all over the world.

The One Great Force. The Cause of Gravitation, Planetary Motion, Heat, Light, Electricity, Magnetism, Chemical Affinity, and other Natural Phenomena. By Crisfield Johnson. Buffalo: Reed & Lent.

The author of this little work first calls attention to the steadily increasing belief among the leaders of the scientific world that heat, light, electricity, magnetism, and chemical affinity are all manifestations of the same force and convertible into each other, and, after reference to Faraday's essay on the "Conservation of Force," and to Grove's doctrine of the correlation of forces, lays down the proposition that "The one great force of the material universe is the self-repulsion of caloric acting on the inertia of ordinary matter." This force, he asserts, is the source or cause of attraction, heat, light, gravitation, capillary attraction, planetary motion, electricity, magnetism, cohesion, adhesion, chemical affinity, combustion, explosion, tides, the building power of animals and plants, and the circulation of the blood. If he does not prove the truth of his proposition, he at least shows the probability of its correctness. We recommend the book to the study of all who take an interest in the subject of the origin of natural forces. *American Artisan.*

Engineering. An Illustrated Weekly Journal. Conducted by Zelah Colburn. London: 1869.

The seventh volume of this most excellent journal is fully up to the previous volumes in extent and quality of matter. We do not see how any engineer who is familiar with Mr. Colburn's writing—his extensive, positive and practical knowledge, and his clear, concise, searching and comprehensive treatment—can do without this journal. In the pretty careful reading of 50 to 70 scientific magazines and newspapers every month, we find much that is thoroughly good and well put, and a great deal that is inconclusive, if not trivial. But we rarely find anything in Mr. Colburn's writings that is not founded upon large views and extensive reading and experience. Even when somewhat hasty and incomplete, as newspaper articles must be, in comparison with exhaustive treatises, Mr. Colburn's articles are full of ideas, apt illustrations and strong points.

A Manual of Elementary Chemistry, Theoretical and Practical. By Geo. Fownes, F. R. S., late Professor of Chemistry in University College, London. Tenth edition, revised and correeted. London: John Churchill & Sons, New Burlington street, 1868.

There is probably not a student of chemistry in this country to whom the admirable manual of the late Professor Fownes is unknown. It has achieved a success which we believe is entirely without a parallel among the scientific text-books in our language. This success has arisen from the fact that there is no English work on chemistry which combines so many excellences. Of convenient size, of attractive form, clear and concise in diction, well illustrated, and of moderate price, it would seem that every requisite for a student's handbook has been attained.—*Chemical News.*

A Synopsis of the Patent Laws of Various Countries. By Alex. Tolhausen, Ph. D., Translator at the Patent-office, London: Trubner & Co.

This work contains, in a condensed form, all the necessary information respecting fees, documents required, disclaimers, prolongation, infringements, jurisdiction, and legal proceedings, &c., &c., together with references to the acts and ordinances themselves. An eager inventor can now ascertain, in a few minutes, the entire cost of patenting his invention in every quarter of the globe.

TRAITÉ ÉLÉMENTAIRE DE PHYSIQUE, PAR A. PRIVAT DESCHANEL, Professor au Lycée Louis le Grand. Paris: 1868.

This work would have been called a "Natural Philosophy" in our school days, but it is rather in advance of the "Comstock's Philosophy" we studied, in style and treatment. It appears to be even an improvement on Ganot, which is saying a great deal. We hope it will be translated, and, above all, that the wood-cuts will be reproduced in something like the French style of high art. The pre-corlissite treatment of the steam engine, for instance, in most of our modern text books, and the pre-raphaelite wood-cuts that disfigure them, are unworthy of the aspirations of American youth, and the pretensions of American publishers.

ELEMENTARY GEOMETRY. By J. M. WILSON, M. A., Fellow of St. John's College, Cambridge, and Mathematical Master at Rugby School. Macmillan & Co.

This is an attempt considered very promising by reviewers, to render an exceedingly dry subject attractive, and hence familiar and useful. The arrangement and treatment of the facts are changed, and practical applications of geometry are introduced. Several attempts had previously been made in England to make Euclid more practical, but they have not been very successful there. In France, on the contrary, Legendre and La Croix each composed elements which have completely supplanted Euclid. It is their models that Wilson has greatly followed.

ART OF CONSTRUCTING AND REPAIRING COMMON ROADS. Weale's Rudimentary Series. London: Virtue & Co., 1868.

A fourth edition of this volume of Weale's Rudimentary Series, with additions, has been published. It includes a "Survey of the Metropolitan Roads," by S. Hughes (which might be left out without much loss); the "Art of Coustructing Common Roads," by Henry Law; "Remarks on the Maintainance of Macadamized Roads," by Sir John Burgoyne; and a note by Mr. Robert Mallet on the causes of the apparent failure of macadamized roads in certain localities. Mr. Mallett regards asphaltic macadamizing as the very best material for the street surfaces of populous cities. A large amount of valuable instruction is given.

MOLECULAR AND MICROSCOPIC SCIENCE.—By MARY SOMERVILLE, in two volumes. London: John Murray. 1869.

The scope of the work is thus stated in the preface: "Microscopic investigation, organic and inorganic, is so peculiarly characteristic of the actual state of science, that the author has ventured to give a sketch of some of the most prominent discoveries in the life and structure of the lower vegetable and marine animals, in addition to a few of those regarding inert matter." The work is quite fully illustrated.

THE MONTHLY MICROSCOPICAL JOURNAL.—TRANSACTIONS OF THE ROYAL MICROSCOPICAL SOCIETY, AND RECORD OF HISTOLOGICAL RESEARCH AT HOME A D ABROAD. Edited by HENRY LAWSON, M. D., F. R. M. S., London. No. 1, Jan. 1869. This is a new illustrated Journal of this important and growing science.

TABLES SHOWING THE LENGTH, IN FEET, OF A DEGREE, MINUTE, AND SECOND OF LATITUDE AND LONGITUDE, WITH THE CORRESPONDING NUMBER OF STATUTE MILES IN EACH DEGREE OF LATITUDE, &c., &c. By R. C. CARRINGTON, F. R. G. S., of the Hydrographic Department of the Admiralty.

QUANTITIES MADE EASY; A QUICK AND ACCURATE METHOD OF TAKING OUT QUANTITIES IN BUILDINGS. By H. A. CREASEY. F. SHAW, Dockhead.

These pages consist of lists of tho items in an ordinary dwelling house, so that an estimator may not forget or overlook any in taking out his quantities. Instead, however, of keeping all the trades separate, the writer puts each room separately, so that the same headings would have to be written over and over again, and the resulting sum would be very much higher than the same estimator would bring to it if he pursued the more customary, expeditious and common-sense mode.

A TEXT-BOOK OF NATURAL PHILOSOPHY. An accurate Modern and Systematic Explanation of the Elementary Principles of the Science. Adapted to use in High Schools and Academies. With 149 illustrations. By LE ROY C. COOLEY, A. M., Prof. of Nat. Scienco in the N. Y. State Normal School. Pp. 315. New York: Charles Scribner & Co., 654 Broadway.

The author discourses of molecules and molecular motions, having cut adrift the ancient theory of imponderables. He has no respect for error because it is venerable, and he gives it no room in his book. He sets a good example to the *compilers* of school-books of science.—*Chemical News.*

DICTIONARY OF ENGINEERING, CIVIL, MECHANICAL, MILITARY, AND NAVAL, WITH TECHNICAL TERMS IN FRENCH, GERMAN, ITALIAN AND SPANISH. E. & F. N. Spon. London: 1869. Part I.

This work appears, upon a cursory examination, to be full of useful and *modern* practice. It is very liberally and well illustrated. The "Engineer" and other authorities criticise some of its articles very freely, but all of them, on the whole, commend it. It cannot fail to be important and valuable.

UNDERGROUND LIFE, OR MINES AND MINERS. By L. SIMONIN. TRANSLATED, ADAPTED TO THE PRESENT STATE OF BRITISH MINING, AND EDITED BY H. W. BRISTOW, F. R. S., of the Geological Survey. Illustrated with many plates, including chromo-lithographs. London: Chapman & Hall, 1869.

This is a beautifully printed and illustrated work, and will prove very entertaining to all readers, professional or otherwise.

THE RAILWAYS OF INDIA, WITH AN ACCOUNT OF THEIR RISE, PROGRESS AND CONSTRUCTION; WRITTEN WITH THE AID OF THE RECORDS OF THE INDIA OFFICE. By EDWARD DAVISON, Captain, R. N. London: E. & F. N. Spon. 1868.

THE CHEMICAL NEWS, Vol. IX, 1869. The papers in this volume are, so far, interesting to all classes of readers, especially the articles on food, sewage and water supply.

SANITARY SIFTINGS, OR RESULTS OF SEWAGE SYSTEMS COMPARED. London: E. and F. N. Spon, Charing Cross.

THE A.B.C. SEWAGE PROCESS. London: Yates & Alexander, 7 Symonds Inn, Chancery Lane.

NAVIGATION AND NAUTICAL ASTRONOMY.—J. Merrifield and H. Evers. 8vo., 14s.

COURS DE CHIMIE AGRICOLE. Par M. G. LECHARTIER. Paris.

VESUVIUS. By JOHN PHILIPS, M. A. Oxford: 1869.

COURS DE MÉCANIQUE. Par M. EMILE LECLERT, Paris.

MISCELLANEOUS.

Moving City Blocks.—In the new Boston improvements, this is accomplished in the following manner: About six houses, or one hundred and twenty feet long, are usually raised in one block together, the walls, front and back, being cut, or rather a line of separation being made at about each sixth house. The raising is done by screws, as usual, and the blocking is the usual cob-house work of pieces of timber. The moving is on wooden rollers, round iron bars, and on balls, with no apparent reason for choosing or using either. Of course, those houses at the ends of each block, in raising, where the party wall is removed, are carefully clamped and braced. And about every fourth house has been found to require the front and back walls to be clamped by through bolts to the floors. The walls may be said to be universally but eight inches—one brick thick. *About one-half the houses are occupied,* the raising or moving not interfering with the domestic comforts of the household. From an examination of the buildings, very few cracks are discernable. The ground is fortunately all solid, not "made," and the underpinning is either done in brick or in cubical granite blocks.

Submarine Blasting at Hell Gate.—The apparatus designed for drilling the sunken rocks for the introduction of the charge, consists of a water-tight iron casing, in form a depressed semi-spheroid, seven feet in diameter. It has three solid steel feet by which its stability on the rock is secured. Rising from the upper part of the casing is a conical wrought iron frame, supporting the upper end of the drill shaft by means of two parallel rods entering into sockets in a cast ring at the top of the frame. The drill bar passing up through the center of the top is furnished at the bottom with a bit, one and a half inches diameter, having imbedded in its face nineteen diamonds, and rotating at the rate of from 300 to 500 revolutions per minute, advancing at the rate of from one to one and a half inches in the same time. The feed is caused by a differential gearing which steadily operates to advance the drill into the rock, the debris being washed away by the water forced into contact with the bit through a small rubber hose. The water-tight chamber of the machine contains a pair of engines working at right angles to each other, with a horizontal stroke. As soon as the hole is completely drilled, and also when the drill shaft is withdrawn from the rock, information of this is given by a magnetic bell which is acted upon by a double wire cord insulated from the water and passing down one of the parallel rods or tubes upon which the crosshead is fixed. This drill weighs nearly five tons. It is worked from a wrecking tug with a derrick by means of steam supplied from the boiler of the tug. To prevent this steam being condensed in its passage through the water to the engine it is conveyed in a hose surrounded by another through which the exhausted steam passes. The rock at Hell Gate is that known as the bastard granite, and is much softer than either the Quincy or Maine granite, on which the drill has been satisfactorily tested. After a number of holes are drilled over a certain space, a diver descends and charges them with cartridges of nitro-glycerine, which is exploded in the usual manner. The fragments are raised by automatic grapnels.

Opinions Differ.—A prominent London cotemporary says about two inventions, one English and the other American, both of which are recognized by the best and most numerous authorities as among the most successful improvements of modern times, as follows:—

Siemens' furnaces do not gain in favor. Those put down at the Woolwich Gun factory are not used, as they were not economical. In Prussia, we understand that they make no way, and the statement is indirectly supported by another which has reached us to the effect that, although used at Elswick, they cost 30 per cent more in fuel than the common furnaces.

Mr. Isherwood, the chief engineer of the United States navy, has reported dead against the monitors, and the secretary of the United States navy cooly suppressed this portion of the report. The American government are building no monitors, and both the Dictator and the Puritan have been pronounced total failures. Turret ships are increasing in favor in Europe, but they must not be confounded with the Ericsson monitor, which is a very different thing.

Trial of Steam Rollers.—A successful public trial has been made at Rochester of a steam road roller, manufactured by Messrs. Aveling and Porter, for the city of New York. An incline having a rise of 1 in 12, was chosen for the trial, its entire surface being covered with the ordinery stones used on macadamised roads. In six hours the road was completely smooth and fit for the passage of vehicles. Messrs. Aveling and Porter have in hand three similar rollers for the Indian authorities.

WESTERN RIVER NAVIGATION.—The Pittsburgh "Chronicle" gives the following figures concerning the number and tonnage owned in the different States along the Mississippi and its tributaries:

	Barges.	Steam vessels.	Total tonnage.
Louisiana	33	230	55,328.67
Mississippi	..	15	2,396.33
Tennessee	..	63	13,412.83
Kentucky	14	75	27,372.83
Missouri	98	210	112,123.18
Iowa	28	28	5,002.29
Minnesota	87	53	18,982.01
Illinois	99	72	27,323.65
Indiana	..	26	5,293.88
Ohio	70	165	98,714.45
West Virginia	20	124	22,115.42
Pennsylvania	385	197	93,152.03
Total	834	1,263	481,217.61

HOT PRESSED NUTS IN ENGLAND.—American machinery for making nuts has been introduced in Birmingham. The process may be thus briefly described: The puddled iron is placed in a reverberatory furnace, rolled to the requisite size, and while still hot is placed in the machines. Here the iron is cut off, forced into a die box, either square, hexagonal, or octagonal, as the case may be, and while under the necessary pressure it is punched simultaneously from either side. The advantages of this process are the greater cohesive strength arising from the hole being forced into the nut, thereby solidifying the metal; the certainty with which the hole is made exactly central, as well as smooth and true throughout; the regularity and quality of the angles; complete uniformity of size; and rapidity of production. Fifty to eighty nuts can be produced per minute. Bolts are produced by other machines at a single blow.

NOVEL USE OF THE CAMERA OBSCURA.—Some officers of engineers have just been making experiments at Antwerp as to the means of defending the passes of the Scheldt by a system of torpedoes placed in three lines, the explosion of which is regulated by the use of a camera obscura. The instrument is fixed at a certain point, and whenever a ship passes over it, its image is reflected on the mirror at the camera. When the image arrives at a certain determined point, the eclectric current is applied, and the explosion takes place immediately. The mines are numbered, and each has a corresponding mark in the chamber. The method of observation is simple and sure, and was adapted for the defence of Venice in the late Italian war. The trials succeeded perfectly, and are soon to be repeated on a larger scale.

TWENTY-FOUR POUND BOAT.—Walter Brown, the champion oarsman, has lately built a single scull outrigger shell of Spanish cedar, 30 feet seven inches long, twelve inches wide, and six and three-eighths inches deep amidships; four feet and eleven inches wide across the rowlocks, eight inches deep aft, and four and a half inches forward; weight 24 pounds. She is nearly finished now, and weighs only eighteen pounds. He is building another boat of the same size, which will weigh only nineteen pounds. The lightest boat heretofore built, of the same size, was that in which Brown rowed at Pittsburg last September. This was made of paper, and weighed $27\frac{1}{2}$ pounds.

SCREWS VS. PADDLE.—The Cunard paddle steamer Persia has been turned into a sailing vessel with auxiliary screw. The Cunard paddle steamer Scotia is to be converted into a screw.

PAPER ON CONSTRUCTION.—We have in type the first of a valuable series of articles on this subject, which will extend through several numbers of the magazine. Various papers on construction are in course of publication, in the home and foreign serials. While they are generally useful, we think that some of them are too elementary, others too abstruse, and others still too limited in scope to meet the requirements of our readers. A compilation of such miscellaneous elements would hardly answer the purpose. We have therefore secured the preparation of a series of *original papers*, by an engineer officer, whose education and practice have thoroughly fitted him for the work.

THE ROGERS LOCOMOTIVE WORKS employ 3,000 hands, and turn out about ten locomotives per month, besides an immense quantity of cotton and woolen machinery. The works comprise one building 200 by 32 feet, and one 102 by 40, with boiler shop, erecting shops and several other structures. This establishment was founded in 1831 by Thomas Rogers, and turned out its first locomotive for the Mad River and Lake Erie Co., in 1838.—*American Railway Times.*

WORKS FOR UNLOADING COAL AT NEW HAVEN.—Hawkins, Herthel and Burrall of Springfield, Mass., have a contract, amounting to upwards of $40,000, for building a new coal wharf for the Hartford and New Haven railroad at New Haven. In connection with the wharf, which is to be 1,000 feet long and 50 feet wide, will be four elevators, capable of storing 1,000 tons of coal.

THE BOSTON ELEVATOR, building by the Boston and Albany Railroad Co., is constructed of brick and wood; it is 70 feet high. The upper story will contain 82 bins; the total capacity will be 250,000 bushels. It is stated that a car can be emptied in ten minutes, and that the cost of elevating and storing will be one cent per bushel for the first five days, and storage extra after that time.

BLASTING GRANITE.—In one of the granite quarries, near Penryn, a large mass of sound granite has been moved from its natural bed some inches, by 50 lb. of blasting powder, confined in a hole 12 ft. deep and $6\frac{1}{2}$ in. in diameter, bored in the rock. The stone measures, at least, 40 ft. by 40 ft. by 12 ft., which equals 19,200 cubic feet, or 1,280 tons.

THE MERCANTILE LIBRARY of New York has now 100,000 volumes, embracing the best works on every topic. Popular works are largely duplicated, and about 10,000 volumes are added yearly. The reading-room is large, well-warmed, well-lighted, and supplied with 3,000 books of reference, and over 400 periodicals, foreign and domestic.

ELECTRIC CLOCKS.—Kennedy's, exhibited in New York, are driven by the current of an earth battery, and require no winding up. All the clocks in a house or locality, or on a line of railway, may, it is alleged, be driven by the same battery, and keep the same time, tick for tick.

STEAMSHIP CONSTRUCTION.—The promised article treating this subject generally, has been crowded out by two articles referring to the marine engine particularly—the Hercules, and Morton's Condenser—but will appear in our next number.

THE P. AND O. FLEET.—The steam fleet owned by the Peninsular and Oriental Company comprises a total of 48 ocean-going vessels, having an aggregate tonnage of 85,632 tons and 18,520 horse power.

FRENCH NAVAL ENGINES.

CRITICISMS AND ANSWERS—LIGHT MARINE ENGINES—HISTORY OF HIGH EXPANSION—NORMAND'S SYSTEM.

Translated from "Annales du Génie Civil."

In our last number we published the sharp criticisms of "Engineering" on our navy. M. Belleville, in a discussion of a memoir of M. Normand, has replied to these criticisms which, under the influence of a patriotic anxiety, have been much exaggerated; and our readers will see that if, as MM. Mallet and Normand have shown, we can improve vastly in the engines used in our ships, we have long been in advance of other nations in the improvements made upon hulls and propellers. MM. Normand and Mallet intended in their memoir to give an accurate *resumé* of all the improvements which have been made in marine engines, and a table showing the progress made at the principal centers of ship building in the Old World and the New, and they proposed to show the arrangements which must be adopted in marine machinery, if we expect to get rid of the errors in vogue among naval engineers. The problem of the best system of marine machinery consists entirely in the determination of the best results in three classes of economy. We give them in the order of their relative importance: 1st. Economy of weight. 2d. Economy of fuel. 3d. Economy in expenses of capital, in repairs, in the *personnel* and accessory expenses. These various kinds of economy are not inconsistent with each other.

MM. Mallet and Normand have summed up in four graphic tables the results obtained by experiment from more than one hundred engines. The first represents the weights of the machinery complete (engine, boiler, water and propeller) in horse powers of 75 kilogrammeters measured by the indicator on the pistons. The second shows the actual development of power measured by the indicator per nominal horse power. The third shows the consumption of fuel per indicated horse power of 75 kil. met. The fourth shows the total weight of the entire machinery, with fuel enough for five days' steaming with maximum power. Each of these tables will show at a glance the great difference in the results given by the various systems which are or which have been in use. We may thus determine the disadvantageous position occupied by the French navy with respect to its prime movers. This inferiority has been general for a quarter of a century, and is continually getting worse. It is an indisputable fact to-day that the English vessels recently built can develop an actual power nearly double that of the vessels in the French fleet. The development per nominal horse power which in the Imperial marine has never yet reached 300 kil. met., is fixed for the new English vessels at 450 and in some of them exceeds 500 kil. met.

The weight of engines per unit of actual power is the most important question, and it is upon this point that the widest differences with respect to economy occur. The total weight of the machinery, including boilers, may be resolved into its elements. The steam generating apparatus, consisting of elements in some sort alike (grates, flues or boilers), differ only in the number of parts. The total weight of boilers and water is then, for each system, sensibly proportional to the power to be developed. In the engine proper the case is different—for the same system the weight varies in a higher ratio than the power. Notwithstanding the many modifications introduced into the construction of engines and boilers, the ratio between the fraction of weight which is always constant, and the fraction which varies with the velocity of the engine, is not sensibly changed. In taking for a unit of weight the weight due to a velocity of one revolution per second, we may express the relation for all other velocities by the formula—

$$P = \frac{2}{3} p + \frac{1}{3n} p.$$

The following figures indicate the total weights per indicated horse power, corresponding to each of the great classes of marine engines:

No. of revolutions per minute	15	20	30	60
Old beam engines with flue boilers	660 kg.	550 kg.	440 kg.	330 kg.
Direct acting engines with tubular boilers.	420	350	280	210
Same engine of John Penn's system	300	250	200	150
Limits of the lightest engines of the present day	240	200	160	120

These figures show the vast progress made during the last 25 years in reducing the weight of machinery. Between the first Cunard packets and the present transatlantic propellers the weight has undergone a reduction from 660 kil. down to 180. This reduction is the result of three forms of progress: 1st. The substitution of tubular for flue boilers. 2d. The substitution of direct acting engines for more complicated ones. 3d. The greater rapidity of revolution, due partially to increase in the velocity of the vessels, but especially to the substitution of the propeller for the paddle. Beside those considerations belonging to the degree of excellence in the construction, such as the forms and proportions of the various parts, the use of stronger materials which will allow a diminished thickness, the weight per unit of power developed, &c., the ultimate economy is largely dependent upon the functional action of the steam upon the engine. The conditions of lightness are much improved in large engines by a more advantageous use of the steam, and by the better draft obtained by high chimneys, which can be employed only on large vessels.

Altogether, the results obtained by MM. Normand and Mallet may be summed up as follows:

The old low-pressure flue boilers weigh, on an average, 250 kil. per indicated horse power, and 20 kil. per kil. of steam per hour. In the greater portion of the boilers of Imperial type, these values are reduced to a mean of at least 140 and 13 respectively. In English machinery these weights are only 110 and 10 kil. respectively. In the boilers of the Francis I, built by M. B. Normand, the exclusively cylindrical forms given to the shells and grates, together with the substitution of steel for iron plate, have reduced the weight to 7 kil. per kil. of steam per hour. The combination of these steam generators with the economically working engine has reduced the weight per indicated horse power to 50 kil.—an economy which has never before been reached in any marine boiler.

M. Normand then proceeds to inquire into the conditions which regulate the weights of the other parts of marine machinery, viz: the engine proper and the propeller. Nearly every part has at least one of its dimensions determined by the intensity of the effort which it is to receive or transmit; the weight of every mechanical part then should be sensibly proportional to the amount of work developed by a single revolution. The final development of power as related to the time being proportional to the rapidity of revolution, which in turn is governed by elements dependent upon the vessel, the correct value of the conditions of lightness will be furnished by an expression which MM. Normand and Mallet have employed for the first time (so far as they know), in these investigations. It consists in approximating the weight to a standard corresponding to a uniform velocity (or speed), the weight being inversely proportional to the power due to two-thirds the number of revolutions. Two tables furnished by MM. Normand and Mallet give the economy of weights in paddle and screw engines. In beam engines with paddles, the weight is 1.5 kil. per kil. met. of indicated work per revolution. This weight is between 1 kil. and .80 kil. in a majority of the modern direct acting engines, and in the lightest on the Penn plan it is as low as .60 kil. The weight per indicated horse power shows some extreme variations in consequence of the introduction of another element of inequality, viz: the variable rate of the engines. The weight corresponding to a horse power of 75 kil. met., which in the old beam engines often reached 350 to 400 kil., does not exceed in the most perfect modern engines 150 kil. for the large ones, nor 100 or even 70 kil. for moderate sized and small ones. Screw engines, even the more recent ones, show similar diversity in the economy of weight. The graphic tables alluded to show clearly the errors and mistakes in construction already pointed out by M. Normand. The engines of the Imperial marine are classed between 1.60 and 1.20 kil. per kil. met. per revolution, while the engines of Penn and Maudslay do not exceed .80 or even .70 kil. For weights per indicated horse power, almost all the engines of the Imperial marine are between 150 and 110 kil., while the English builders just cited do not exceed for the largest engines 70, or perhaps even 60 kil. John Penn, in the yacht Le Grille (engine of small size and great speed), has reduced this weight to 30 kil.

But the question of economy of weight in steam engines is intimately connected with that of the advantageous use of steam and consequent economy of fuel. The once admitted laws of expansion are acknowledged to be incorrect, and the tables of cut-off now in use stand in need of correction. MM. Normand and Mallet present a new table of cut-off which they have collated, keeping in view the three following classes of corrections: 1st. For the reductions of temperature corresponding to varying pressure. 2d. For the portion of steam condensed, which, with the reduced temperature, makes up the loss of heat corresponding to the work done. 3d. For the resisting pressure of the condenser. In the calculation of heat consumed by the work done, each unit of heat (*calorie*) has been calculated as corresponding to 400 kil. met. The back pressure of the condenser, which varies from three to six per cent of the boiler pressure, has been made equal to four per cent of the initial pressure. By economy of agents (*organes*) the authors mean the relation existing between the mean effort of the whole stroke of the piston and the maximum effort under initial pressure. The data of cut-off have been made to correspond with the performance of a majority of marine engines with an admission of $\frac{2}{3}$, and not with an admission over the whole length of stroke. Finally, the table has been calculated for an initial pressure of five atmospheres. The values should be slightly increased for lower pressures and diminished for higher.

It must be inferred from these tables that all engines constructed up to a very recent date, however different in plan, show no differences in the economy of steam, at least as to the maximum useful effect obtainable from it. If differences occur, they are the reverse of economy. Notwithstanding the marked increase in the tension of steam, which in the last 20 years has been raised from $1\frac{1}{2}$ to $2\frac{1}{2}$, or even 3 atmospheres, no economy of fuel has been obtained. On the one hand, the experiments of a $\frac{2}{3}$ expansion have led only to mistakes, and on the other the increase of pressure has been offset by disadvantages in the distribution and condensation of the steam. These disadvantages are most conspicuous in engines at high speed. The ordinary marine engine gives an indicated horse power with a theoretical expense of 12 kil. of steam, which represents a consumption of $1\frac{3}{4}$ to $2\frac{1}{2}$ kil. of coal.

At the commencement of this state of affairs it was conceded that the expansion principle offered a boundless field of improvement. Yet it was thought (and perhaps not wrongly) that it would be well to imitate the most advanced products of ingenuity and use the most economical kinds of engine, particularly the draining engine of Cornonailles and the Woolf engines, the cost of which was about half that of the marine engine of that day. But the objections were many. One of these types was heavy, cumbersome, complicated; the double expansion was impracticable on the water, and the pressure must not exceed a defined limit. Facts have demonstrated that an economically working engine not only can be built within the conditions of weight of engines of high expansion, but that a more perfect action of the steam may be a source of still further progress in the economy of weight.

The following history of progressive improvements is succinctly given by MM. Normand & Mallet.

In 1856 Rowan & Horton constructed marine engines on the Woolf plan, with surface condensers, and working at a pressure of 8 or 9 atmospheres, which, however, was practically found to be inconvenient. Randolph & Elder endeavored to increase the expansion by the use of larger cylinders instead of augmented pressure. They succeeded in obtaining good results with expansion under a pressure not exceeding 3 or perhaps $2\frac{1}{2}$ atmospheres. In 1861, Humphreys, following the same path, introduced engines with large cylinders, having small ones superposed. The English engine builders all agree in using a large amount of expansion with surface condensers, steam jackets and superheating. Lastly, M. Normand claims to be the representative of French ingenuity in this struggle for maritime progress, and some significant facts seem to show that the improvements which he was the first to elaborate and carry forward successfully cover the greater part of the problem of the economical marine engine. His attempts go back as far as 1854. The main idea in the Normand system consists in dividing the total expansion between two cylinders, which are entirely independent of each other in respect to their movements, though capable of attachment to the same shaft by cranks at right angles, an essential feature in the marine engine. These cylinders communicate with an intermediate reservoir, where the steam escaping from the first cylinder is relieved of the condensation resulting from the work done, and receives a certain addition of heat before entering the second cylinder. This simple plan constitutes a marine engine with all the advantages of a double expansion and without any increase in the number of parts. It can with suitable modification be applied to any existing engine, and has already been used in small vessels of high speed. With respect to economy of steam its superiority is very decided. With a cut-off at $\frac{1}{4}$, the economy is .92 against .52 in ordinary engines. With a cut-off at $\frac{1}{10}$, the economy is still .54 against .26. The average admission in the two cylinders of M. Normand was in the first .65 and in the second .40.

The advantages of M. Normand's system were officially recognized in 1860 by a commission appointed by the minister of the marine. One of his engines was placed upon the transport Loiret, of the Imperial navy. It had the double expansion, the independent movement of the pistons, with the intermediate reservoir for drying and reheating the steam. Subsequently it was put into a number of frigates with 950 nominal horse power, and into four corvettes, with 450 nominal horse power, &c., &c. He has also applied his system to some fifty engines, marine and stationary, with even better results than those obtained in the navy, though the principles are the same. It was in some engines built in the government dock yards that he obtained the highest actual power, and that with a large expansion and no increase in the size of the cylinders, making a saving of 500 indicated horse power. This is the mean deficiency of the armored frigates, and it serves to show how erroneous have heretofore been the principles upon which their engines were constructed.

With respect to economy of fuel, results have been more favorable. The consumption has been reduced to 1.44 kil., while in the engines built by M. Normand himself this consumption is still less by one-fourth. We give below the relative values of the cut-off in various systems:

	Cut-off at—	Saving.
Old marine engines . . .	$\frac{2}{3}$	1.
Dupuy de Lôme	$\frac{2}{5}$	1.30
Normand	$\frac{2}{9}$	1.60
Humphreys	$\frac{1}{6}$	1.74
Rowan & Horton	$\frac{1}{8}$	1.84
Randolph & Elder . . .	$\frac{1}{10}$	1.90

If it is desired to obtain the greatest lightness of engine with the greatest economy of fuel, the cut-off should be varied according to the distance to be run. M. Normand gives the following table:

1 day,	rate of	expansion,	4 or	5	volumes.
5 "	"	"	5 or	6	"
10 "	"	"	6 or	7	"
15 "	"	"	7 or	8	"
20 "	"	"	8 or	10	"

In view of the faulty imitations of his work, M. Normand finds great pleasure in presenting the results of an engine put into the Francis I—a passenger vessel running between Havre and Trouville, or Honfleur. The nominal power is 100 and the developed power 550; consumption of fuel per indicated horse power, 1.10 kil.; speed, 26 kilometers; boilèr pressure (*le timbre des chaudières*), 4 atmospheres. Total weight of machinery, including 11,000 kil. of water, 56,500 kil.

The Normand system has just been adopted by the General Transatlantic Company for their packets of 450 horse power, which are to be built for their new Pacific line.

As a supplement to the communication of M. Normand, and his observations on the law of the pressure of expanding steam, M. Duprez has published the results of some calculations relative to the work of 1 kilogramme of steam in high pressure engines without condensers, and where the expansion is carried on until the tension becomes equal to 1 atmosphere. The following are the resulting ratios of heat utilized to heat expended:

Initial pressure in atmospheres	8	10	12
Ratios	0.1501	0.1633	0.1771

Hence the increase of useful effect would be 18 per cent if the pressure were carried to 12 atmospheres instead of 8; in other words an engine working at 8 atmospheres and consuming 100 kil. of coal would consume only 84.7 at a pressure of 12 atmospheres, with an expansion to a pressure of 1 atmosphere. The advantage would be still greater if the final pressure were as low as it is in marine engines. These results are in accordance with the method laid down in the work of M. Combes on the mechanical theory of heat, but it assumes that there is no loss of heat by conduction and radiation.

M. Belleville, who has been connected with the Imperial marine since 1853, has obtained meantime some accounts which he thinks do not harmonize altogether with the views of MM. Normand & Mallett. The value of a war vessel does not depend solely upon the greater or less effective force of her engines as compared with their nominal power, nor yet upon the diminished weight of machinery, but as well upon the economy of power, speed obtained, facility of evolution, resources of battery—in short, upon whatever determines fighting qualities and seaworthiness. In 1850 no navy in the world had steam vessels capable of competing with the old sailing craft. England had three or four steamers used as a coast guard, which might sail, with steam alone, 7 knots. At this juncture was launched at Toulon the first steamer which was to solve the vexed problem of great speed united to all of the sea qualities possessed by the better class of sailing vessels. The Napoleon, a product solely of French naval engineering, and furnished with an engine of 900 horse power (nominal), the largest then in existence, has justified all expectations. This purely French achievement served as the type for the creation of new fleets, both in France and elsewhere, and the Napoleon is still considered one of the best wooden war steamers afloat. Her excellent results have been achieved not only in experiments but in actual service. During the Crimean war, when the French squadron were ordered to pass the Dardanelles, the Napoleon, having in tow the three-decker Ville de Paris, accomplished it easily in the face of a powerful head wind which compelled the English fleet to anchor and wait a whole week for favorable weather. After the launch of the Napoleon, England put the Agamemnon upon the stocks—a vessel of the Napoleon type, of almost identical dimensions, and differing only in a little lighter draught. The Napoleon had 2.602 indicated horse power, the Agamemnon 2.206; the speed of the former is 13 knots, of the latter 10 knots. The co-efficients of useful effect are respectively 2.125 and 1.86. In France all vessels put upon the stocks by the Imperial marine were built upon the plan of the Napoleon. In England the same sort of idea was followed, with some variations. The experimental vessels Algesiras and Marlborough offered a further comparison:

	Ind. H.P.	Speed.	Useful effect.
Algesiras	2,696	13.37	2.244
Marlborough	2,718	11.5	1.86

With one-half fires the Algesiras gave 1.742 horse power and 11.66 knots, with a coefficient of useful effect 2.306.

In 1856 the French naval engineers built the armored frigate La Gloire—an undertaking ridiculed by English engineers and scribblers. Their criticisms also became known in France. But the results have vindicated the promoters of this bold project. The plated floating batteries which had been built in France and England after the Crimean war were merely floating forts, while armored vessels having the sea going qualities of wooden ones were then altogether unknown. In this matter England followed the example we set her, and started the construction of a fleet upon our new ideas.

M. Belleville has acquainted us with the composition of the two fleets, showing for each vessel the power, speed and coefficient of useful effect, and from his tables he derives the following mean results for armored vessels:

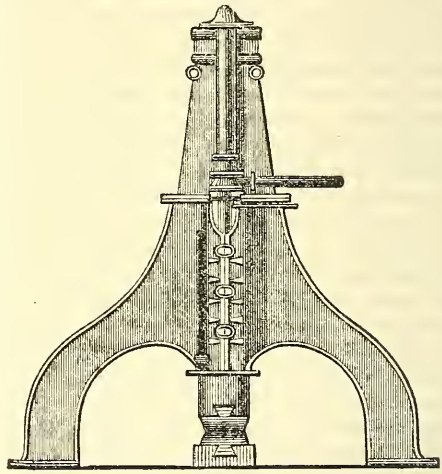
	Speed, knots.	Coeff. of useful effect.
French	13.718	2.176
English	12.939	1.878

On the whole France has led the march of improvement for the last 15 years. Successive engines have been perfected in the Imperial works in which the weight has been reduced and the consumption of fuel decreased. At present the Woolf engines are used, and the consumption of fuel has been reduced to 1.3 kil. on the Magnanime, and to 1.240 kil. on the Jeanne d'Arc, and that without surface condensers. M. Belleville is confident that all the new engines will be provided with surface condensers, and that before long steam at high pressure will also be used, which has not yet been done except upon gunboats and similar structures. Finally, M. Bellville believes that M. Normand's figures relating to the indicated power of the French fleet are too small, while those relating to consumption and to the weights are too large. M. Flachat remarked that M. Belleville did not answer directly the observations of MM. Normand and Mallet, who had examined exhaustively only the marine engine.

Progress in this branch of science has been gradual. First came the screw, with engines of quick stroke and consequently small dimensions; then steam jackets, superheating, surface condensation, and finally high pressure with high expansion. The surface condenser enables the boiler to be fed with distilled water, and prevents incrustation, making the iron plates better conductors of heat and more durable. This step in advance was accomplished in England by MM. Randolph and Elder, but M. Normand had urged it long before, and has finally established it in France in the face of difficulties which the Englishmen did not have to encounter. M. Flachat reviews the successive transformations of marine steam engines, and shows that the Transatlantic Company, whose origin does not go far back, is now making its third transformation. After nine years' service the Royal Mail is also, after a most varied experience, exchanging paddles for screws, with the boilers of Randolph and Elder. The history of the Imperial Company, of the Peninsula and Oriental, of the Cunard—in short, of all companies, is but a long series of renovations and progress. This summary of facts which daily modify our naval material shows the technical importance of the questions to which MM. Normand and Mallet have drawn the attention of the Society. In England progress in this path is very rapid, but in France there are administrative regulations applying to the marine boiler of large diameter and high pressure. It is fortunate that locomotive engines have smoothed the way in this respect, and that the recent progress in the fabrication of plate iron came seasonably to aid in the solution of this question.

MM. Normand and Mallet present some remarks in reply to the strictures of MM. Belleville and Flachat. They state that M. Belleville speaks of vessels in their *ensemble*, while they have confined their investigations to the machinery. They accept some numerical corrections of M. Belleville, as to the power of engines, but insist the correctness of the sources whence they derive their figures should be admitted. They adhere to what they have said as to the inferiority of French engines, in which the useful effect reaches but two-thirds or perhaps only one-half the standard of the English marine.

IMPROVED STEAM HAMMER.—The engraving shows a new style of fifteen ton steam hammer, by Messrs. Thwaites & Carbutt, of Bradford, England.

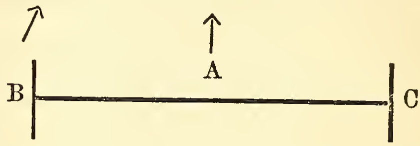


The peculiarity of this hammer consists in joining the standards, which are of the best patterns, boring them out, and putting in a round core. This gives great strength and stiffness, besides more efficiently guiding the hammer. The standards, which are 20 tons in weight, are 20 ft. apart, and give 8 ft. 6 in. headroom. These are bolted to a bed plate made in three pieces, and are also fastened by wedges driven between the lugs, which are cast on the plate. A balance piston valve is placed in the same casting as the stop valve, so as to save the joints of a separate stop valve. The anvil weighs 120 tons, and is placed on two rows of 18 in. sq. oak, laid in a cut stone foundation. The foundation of the block is kept as separate as possible from the side-wall foundations for the bed plate which carries the standard, so that the jerk and spring of the one is not communicated to the other.

IMPROVED RAILWAY RUNNING GEAR—LOOSE WHEELS.

Among the many barbarisms that characterize our railway practice, the sliding of half the wheels in a train, upon every curve in the line, by reason of their rigid connection to the axle, is one of the most wasteful, although it has been one of the most difficult to overcome. Lines of easy curves are not exempted from the evils resulting from the greater length of the outer rail. It is not so much the sliding of a wheel a few feet more or less, after it is started, but it is the starting of the slipping, that consumes power and material, and brings the sudden and heavy torsional strain upon the axle. Even on air lines, the difference in the diameter of wheels—often amounting to ½ inch in one revolution—keeps the axle in an almost perpetual state of torsional strain, and wears the tread of both rail and wheel by an unbroken series of little scrapings, from one end of the road to the other. But the wear is not the only evil. The lurching and jarring of the whole running gear from this cause, and more especially the twisting of the axle back and forth at every curve, thus seriously weakening an iron axle, if not excessively heavy, require a degree of massiveness and non-paying load that could be greatly reduced by making the wheels independent. Precisely what the saving in friction might be, it is impossible to state, because we have no prolonged tests of a thoroughly practicable apparatus. But it is reasonable to assume that with the present apparatus the friction and the general wear and tear of running gear, and the extra non-paying load thereby made necessary, add at least 20 per cent to the normal power required for traction.

Many devices to meet this difficulty have been tried, and many more have been invented. The most obvious direction of improvement is in using a simple loose wheel. One wheel has been cast with a deep hub, so as to give a long bearing on the shaft, and some experimenters have even gone to the trouble of fitting boxes into the hub to take up the wear. But after every nicety of fitting and adjustment, the car had a perverse, uniform, incurable, and, to most experimenters, inexplicable tendency to run off the track; the wheel fastened to the axle was always crowding the rail. This tendency cannot be cured; it can only be avoided by abandoning this plan altogether. A simple analysis of the forces will make this evident. The two axle-boxes and the superincumbent load rest upon the two ends of a continuous axle. Upon one end of this axle a wheel is rigidly fastened; upon the other end there is a loose wheel. In the first place let us suppose that the axle, B C in the diagram, instead of being free to move in the axle-boxes, is rigidly held by them, so that it cannot turn. A power is applied, in the direction A, to the middle of the truck. Since the wheel C cannot turn,



it will tend to slide, and thus require a great exertion of power. But the wheel B can turn, and the end B of the axle, and with it the truck, will be pulled in the direction of the arrow B, while the end C will stand still. It is a simple case of a lever with the fulcrum at C and the power at A. Now, if we loosen the axle-boxes a little, so that the axle will just be able to turn in them, the effect will be the same in kind, but less in degree. The power required to turn the axle in the axle-boxes is still so much in excess of the power required to turn the loose wheel B on the axle, that the end C will be retarded and the truck will run off the track. Just in proportion to the amount of axle friction, will this be the tendency. The forward motion of one side of the truck, or one end of the axle, is retarded by the friction of *both* journals.

This difficulty may, indeed, be avoided by making both wheels loose, but the cost and weight of an apparatus which should give sufficiently long bearings, for safety and stability, would be considerable. Another plan is the division of the axle in the center. The sleeve joining the two ends must be so long and heavy, and the fittings and details for oiling, adjustment, etc., so expensive, that two internal journal-boxes, on a middle beam of the truck frame would perhaps be a better arrangement, and this would be neither cheap nor light.

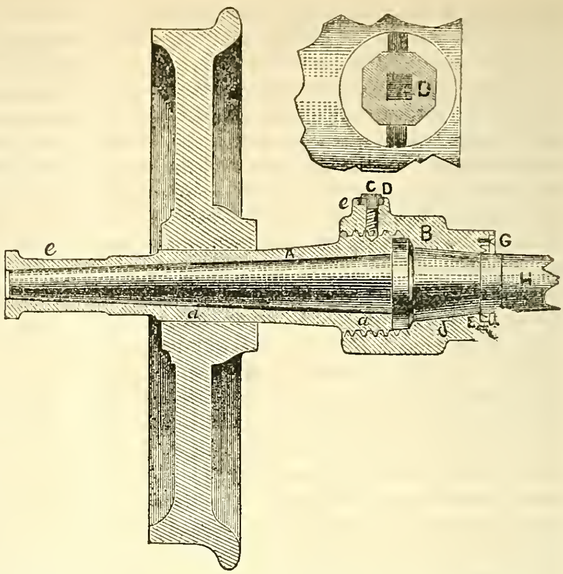
The difficulties we have mentioned have been, we think, very successfully avoided in the axle shown in the engraving.* It is

* Patented by D. M. and A. G. Cummings. Proprietors, Cummings, Wells & Godfrey, Enfield, N. H.

simply a solid iron or steel axle, made smaller at one end to receive a loose steel sleeve, upon which the wheel is fastened, and upon which also the journal-box rests. The opposite wheel is made fast to the axle in the usual manner. The sleeve is 24 in. long, bored at the ends to fit the axle, but counter-bored slightly in the middle to give slight flexibility. The small end of the axle is $1\frac{3}{4}$ in. diameter; the large end of the taper is $3\frac{3}{4}$ in diameter. At this point there is a 6 in. fast collar, from which the axle tapers the other way towards its center. The steel sleeve is held against the collar by a loose collar B, eight inches long, which is screwed upon the end of the steel sleeve. The axle is of the full size, where this loose collar comes, so that the strength is not dependent upon the latter. The collar, however, increases the length of the bearing of the steel sleeve upon the axle to 30 in. The loose collar is kept from unscrewing by the three set screws C (shown in plan in the upper figure), and these set screws are kept from unscrewing, by a washer D fitting into the recessed boss c of the loose collar B. By slightly riveting the opposite corners of the set screw over the washer, the latter is kept in place. Should the bearing between the axle and the steel collar wear, the lost motion may be taken up by withdrawing the set screws, facing off the end of the steel sleeve, and screwing up the loose collar. Oil from the axle-box will be constantly thrown, by centrifugal force, up the inclined portion of the axle, so as to keep all these parts lubricated. The oil may be prevented from escaping, and dust from entering, at H, by means of a hydraulic packing leather and plate G, F. The details have been very thoroughly worked out by a skillful mechanic.

It will be observed that the strength of the axle is not impaired. Although the internal axle is small, the external steel sleeve brings the whole structure up to full size. Experiments upon hollow axles show that the sleeve would be nearly or quite as strong bored out as if solid. The additional weight is chiefly that of the loose collar B.

We learn that several sets of these axles are being fitted up for trial on the Pennsylvania and other roads.



STEAMSHIP PERFORMANCE—THE KŒNIG WILHELM.

In a previous number* we gave the particulars and performances of one of Mr. Reed's new iron-clads—the Hercules. The remarkable results of Messrs. Penn's engines, in this vessel, have been largely commented upon in the technical press. We now quote from "Engineering" some particulars of another of Mr. Reed's vessels—the Kœnig Wilhelm, a new Prussian iron-clad—and the results of the engines of Messrs. Maudslay, Sons and Field, builders of equal renown.

This vessel is 372 ft. 4 in. long over all, and 355 ft. 10 in. between perpendiculars, with 60 ft. beam; being 30 ft. 10 in. longer and 1 ft. broader than the Hercules, while her tonnage is $5{,}938\frac{71}{94}$ tons, being nearly 705 tons in excess of that of the last named vessel. She is provided with an armored battery commencing 42 ft. aft of the fore perpendicular and extending for a length of 232 ft. on the main deck, this battery being protected at the sides with 8 in. armor plates, and at the ends by plates 6 in. and $5\frac{1}{2}$ in. thick. Besides this main battery there is an after battery protected with 6 in. plates, and having a port pointing directly astern; and also armor plated bulkheads on the upper deck. At the water line the Kœnig Wilhelm is protected by a belt

* Van Nostrand's Magazine, Vol. I, No. 3, p. 204.

of armor plating of which the lower edge is 6 ft. 8 in. below the water line amidships and a little less forward, whilst under the counter it rises considerably. The lower strake of this belt is composed of plates 7 in. thick amidships and tapering to 5 in. thick at the extremities, while the remainder consists of plates 8 in. thick amidships, tapering to 6 in. fore and aft. From the particulars we have just given it will be seen that the Kœnig Wilhelm is less heavily plated at the water line than the Hercules, while over the upper part or battery the armor is slightly heavier than that of the latter vessel. The port sills of the Kœnig Wilhelm are 10 ft. above the water line amidships, while those of the Hercules are 11 ft.; and there can be no doubt that the additional free board possessed by the latter vessel would prove of great advantage to her in the event of an action in rough water.

The Kœnig Wilhelm is fitted with a set of three-cylinder engines, by Messrs. Maudslay, Sons and Field, and we think that the performance of these engines during the recent trial must have given unqualified satisfaction to their makers and to all concerned. The cylinders are 95 in. in diameter, with 4 ft. 6 in. stroke, and during the trial they were run at a mean speed of 64 revolutions, and a maximum speed of 65.333 revolutions per minute, corresponding to piston speeds of 576 ft. and 588.117 ft. per minute respectively. The engines are fitted with surface condensers, exposing 17,250 square feet of surface; and steam is supplied by eight boilers, having 22,600 square feet of heating surface, and a fire-grate area of 890 square feet. Although rated at but 1,150 nominal horse power, the engines developed during the trial a mean indicated power of 8,345 horses, whilst during the running of the sixth mile the indicated power reached no less than 8,663.889 horse power, the highest result, so far as we are aware, ever obtained on shipboard with any engines, or under any circumstances; and one on which we think Messrs. Maudslay may fairly be congratulated. We give, on another page of the present number, engravings of the indicator diagrams taken during the sixth run, when the above power was developed, and to these and the particulars which accompany them we refer for more detailed information concerning the performance.

As we have already instituted a general comparison between the Kœnig Wilhelm and the Hercules, it may be interesting that we should similarly compare the engines of the two vessels, constructed as they have been by our two leading firms of marine engine builders. The principal results obtained during the respective trials were as follows:

	Hercules, engined by Penn.	Kœnig Wilhelm, engined by Maudslay.
Revolutions per min, max.......	72	65.333
" " mean......	71.51	64
Piston speed in feet per min, max.,	648	588.117
" " mean,	613.59	576
Mean pressure of steam in boilers,	29.5 lb.	30.5 lb.
" " cylinders,	20.0 lb.	22.483 lb.
Average vacuum*................	27.08 in	27.875 in
Nominal horse power	1200 H.P.	1150 H.P.
Mean indicated horse power	8528.75 H.P.	8345 H.P.
Maximum	?	8663 889H.P.
Number of times the mean indicated exceeds the nominal horse power........................	7.106	7.256

The proportions of heating and condensing surface and fire-grate area to the power developed in the two sets of engines are as follows:

	Square feet per mean indicated horse power.	
	Hercules.	Kœnig Wilhelm.
Heating surface................	2.7	2.9
Fire-grate area................	0.106	0.108
Condensing surface............	2.43	2.067

The draught of the Kœnig Wilhelm, on the occasion of her trial, was 24 ft. $4\frac{1}{2}$ in. forward and 26 ft. $4\frac{1}{2}$ in. aft, while her displacement was 9,542 tons, or 862 tons more than that of the Hercules during the corresponding trial. The area of immersed midship section, on the other hand, was 1,306 square feet, or 9 square feet less than that of the Hercules. For the particulars of the speed attained during the different runs, we must refer to page 135 of the present number, where these details are given, and we need only state here that the true mean speed, as determined by the "mean of means," was 14.499 knots against the speed of 14.691 knots attained by the Hercules. The coefficients given by the respective full power trials of the two vessels are as follows:

	Hercules.	Kœnig Wilhelm.
$\frac{\text{Speed}^3 \times \text{mid. sec.}}{\text{Ind. H.P.}}$	488	477
$\frac{\text{Speed}^3 \times \text{disp.}^{\frac{2}{3}}}{\text{Ind. H.P.}}$	157	164.3

It is, we think, unnecessary that we should comment upon the facts we have laid before our readers, as the remarks which we have on previous occasions made concerning the

* The weather barometer stood at 30.2 in. on the occasion of the trial of the Hercules, and 30.4 in. on that of the Kœnig Wilhelm.

Hercules will apply almost equally well to the Kœnig Wilhelm. This being the case, we need only say that we consider that to Mr. Reed is due the credit of having produced in these vessels the two finest ironclads afloat; and while we cannot but congratulate the Prussians on the possession of the Kœnig Wilhelm, we still more congratulate ourselves on the possession, in the Hercules, of a vessel which we believe to be, in many respects, her decided superior.

NEW ENGLISH LOCOMOTIVES.

In reviewing the late locomotive practice in England, "The Engineer" says that little or nothing has been done that was not done before. The relative merits of inside and outside cylinders remain in dispute. On the Great Eastern system, where Mr. Sinclair employed outside cylinders solely, Mr. Johnson, his successor, is building nothing but inside cylinders, while Mr. Adams, of the North London Railway, who built only inside cylinder engines, is now using outside cylinders. We mention these facts simply to illustrate the diversity of opinion which exists all over the kingdom on this point. So long as cylinders can be kept down to a diameter of about 16 in. the advantage seems to be with the inside type. The 4 ft. 8½ in. guage is too narrow for cylinders of larger diameter, unless the valve boxes are pushed out of their legitimate place, or the valves are left unbalanced.

The following are the particulars of some new standard engines:

FOUR WHEEL COUPLED LOCOMOTIVE,

built for the Great Southern and Western Railway of Ireland at the Company's works at Inchicore, Dublin, from the designs of Mr. A. M'Donnell, the locomotive superintendent of the line. This engine, although possessing no striking peculiarities, is yet well worthy of attention as a good example of a passenger locomotive for the 5 ft. 3 in. gauge. The engine is simple in construction, and ample bearing surfaces are provided for all working parts; whilst advantage has been taken of the width of the gauge to obtain a good large fire-box. The guide-bars, piston-rods, axles, axle-box guides and axle-boxes are of steel. The principal dimensions of the engine are as follows:

Boiler.	ft.	in.
Diameter of barrel inside smallest plate....	4	0
Length of barrel	9	7
Length of fire-box casing	5	1
Length of inside fire-box at bottom.......	4	6
Width of inside fire-box at bottom........	3	11
Height of inside fire-box at front.........	5	4¼
Height of inside fire-box at back.........	4	8¼
(All dimensions of inside fire-box are inside dimensions.)		
Thickness of barrel and fire-box casing plates	0	0½
Thickness of smoke-box tube plate	0	0¾
Number of tubes 174		
Length of tubes between tube-plates	9	10¼
Diameter of tubes outside tube-plates.....	0	2

Heating Surface.	sq. ft.
Tubes (outside)	887.7
Fire-box	95.45
Total	993.15
Fire-grate area	17.6

Wheels and Axles.	ft.	in.
Diameter of driving wheel................	6	6
Diameter of trailing wheel................	6	0
Diameter of leading wheel................	4	0
Distance between centers of leading and driving wheels	7	0
Distance between centers of driving and trailing wheels	7	9
Total wheel base	14	9
Cylinders.		
Diameter............................	1	4
Stroke..............................	1	10
Distance apart from center to center......	2	6½
Distance apart of frames	4	7

Weight of Engine.			
Empty:	tons.	cwt.	qr.
On leading wheels	9	5	0
On driving wheels	10	4	0
On trailing wheels	9	17	0
Total	29	6	0
In working order:	tons.	cwt.	qr.
On leading wheels	10	5	0
On driving wheels	11	1	0
On trailing wheels	11	1	0
Total	32	7	0

Mr. M'Donnell, we may mention, is now building for his line two double-bogie engines on Mr. Fairlie's plan, these engines having boilers and general details similar to those of the locomotive we illustrate.

SIX COUPLED TANK LOCOMOTIVES,

from the designs of Mr. Samuel Johnson, by Messrs. Ruston, Proctor and Co., of Lincoln, for the Great Eastern Railway. These engines are intended more especially for shunting purposes, for which they are excellently adapted. The cylinders, which are inside, are placed at an inclination of 1 in 10, this being just sufficient to enable the guide-bars to be kept clear of the leading axle. The water is carried in a pair of wing tanks, and the fuel in a coal box at the back of the foot-plate, a cast-iron balance weight being placed beneath the latter to increase the weight on the hind wheels. The leading and driving springs are arranged above the axle-boxes in the ordinary way; but at the trailing end the weight is carried by a transverse spring placed behind the fire-box. In some six-coupled goods engines, with tenders, recently built from Mr. Johnson's designs, a transverse spring is also used at the hind end, whilst the leading and driving springs are connected by compensating beams, so the engines are carried on three points, the transverse spring of course acting as a compensating beam between the two bearings of the trailing axle. In the construction of these engines steel has been largely employed, the horn-blocks, slide-bars, piston-rods, crank-pins and tyres being all of Messrs. Vickers, Sons and Co.'s crucible steel. The barrel of the boiler is made of two plates, butt-jointed above the water line. The principal dimensions of the engines are as follows:

Cylinders.	ft.	in.
Diameter	1	4
Stroke	1	10
Distance apart from center to center	2	4
Length of ports	1	2
Width of exhaust ports	0	3
Width of steam	0	1¼
Width of bars	0	1
Distance from center of driving axle to center of exhaust port	8	10
Working Gear.		
Length of connecting rods between centers,	5	6
Diameter of bearing at large end	0	7
Length of bearing at large end	0	4
Diameter of bearing at small end	0	3
Length of bearing at small end	0	3
Width of guide bars (double)	0	2¾
Length of crosshead blocks	0	9
Diameter of piston rods	0	2¾
Diameter of valve spindles	0	1¾
Distance between centers of valve spindles,	0	4
Boiler.		
Diameter of barrel (inside)	3	9
Length of barrel (inside)	9	1
Length of fire-box casing (outside)	4	4¾
Width of fire-box casing	3	11
Depth at front below center line of boiler,	4	5½
Length of inside fire-box at top	3	8
Length of inside fire-box at bottom	3	9
Width of inside fire-box at bottom	3	4
Height of inside fire-box at front	5	0
Number of tubes 124		
Diameter of tubes (outside)	0	2
Length of tubes between tube-plates	9	4 1/16
Diameter of blast nozzle	0	4¾
	ft.	in.
Diameter of chimney at top	1	3
Diameter of chimney at bottom	1	4
Heating Surface.	sq. ft.	
Fire-box	70.8	
Tubes	608.2	
Total	679.0	
Fire-grate area	12.5	
Tanks.	ft.	in.
Length of side tanks	10	0
Height of side tanks	4	3½
Width of side tanks at widest part	1	6
Contents of tanks .... 778 gallons.		
Length of coal box	2	0
Width of coal box	7	3¾
Wheels and Axles.		
Diameter of wheels	4	0
Distance between centers of leading and driving wheels	6	9
Distance between centers of driving and trailing wheels	6	9
Total wheel base	13	6
Bearings of Driving Axles.		
Length	0	7
Diameter	0	6¾
Distance apart from center to center	3	11½
Diameter of axle between cranks	0	6¾
Bearings of Leading and Trailing Axles.		
Length	0	6¾
Diameter at center	0	6
Diameter at ends	0	7
Distance between centers of bearings of leading axle	3	11
Distance between centers of bearings of trailing axles	3	10
Diameter of leading and trailing axles at centers	0	6
Frames.		
Length inside buffer beams	22	6
Distance apart	4	1
Thickness	0	1⅛
Depth (extreme)	2	7¼
Width over footplate at leading end	7	7
Width over footplate at trailing end	8	4

The weight of these engines is about 35 tons in working order, and they will exert a tractive force, less the internal resistances, of 117.3 lb. for each pound of effective pressure per square inch on the pistons. Thus with a mean effective pressure of 98 lb. per square inch they would exert a tractive force of about 11,500 lb. The boiler is worked at a pressure of 140 lb. per square inch, and is fed by a pair of injectors.

The engines we have described are, as we have said, well adapted for the work for which they are intended; and we understand that their performance has proved exceedingly satisfactory.

STEEL RAILS.

STANDARD PATTERNS ILLUSTRATED.

The sections of rails shown on the opposite page, embrace some of the best patterns, of various weights. The engravings (excepting fig. 3) are half size, and are made accurately to scale. The patterns are as follows :

FIG. 1.—65 *lb. Erie Rail.*—Of this pattern, some 1,000 tons had been made, on a large order, for the Erie road, by Messrs. John A. Griswold & Co., Troy, up to October last, when the converting works were destroyed by fire.

FIG. 2.—56 *lb. Penn. Railroad Pattern.*—This rail was designed by Mr. J. Edgar Thompson, President of the Pennsylvania Railroad, but a heavier pattern (fig. 4) has thus far been adopted on that line. Of the 56 lb. pattern, the Pennsylvania Steel Company have made some thousand tons for various roads—the Pittsburg, Fort Wayne and Chicago ; the Michigan Southern, &c. Messrs. John A. Griswold & Co. have made about the same quantity of the same pattern for the Chicago and Northwestern, Rensselaer and Saratoga, and other lines. This may be called a favorite pattern. It is high enough to be fished to advantage, and well shaped for this purpose.

FIG. 3.—80 *lb. Paris and Lyons Railway.*—This pattern is specially intended for fishing, though we consider the required angle of the fish plate bearing too great; too great a strain would be brought upon the bolts. The rail below it (fig. 5) is much better in this regard. We think a wider head would also be preferable. But the base is very wide—$5\frac{1}{8}$ in., and affords an excellent bearing on the sleepers. The rails are 19 ft. $8\frac{1}{4}$ in. long each. Their ends are unsupported, the distance between the sleepers, between which the joint is situated, being $23\frac{3}{4}$ in. The sleepers next are at a distance of 2 ft. $3\frac{1}{2}$ in., and the others of 2 ft. $7\frac{1}{2}$ in. This gives eight sleepers per rail. The sleepers are made of ordinary, not of hard, sorts of wood. The dimensions of sleepers are : length, 8 ft. 6 in. to 9 ft. 2 in.; breadth, $7\frac{7}{8}$ in. ; height or thickness between, $5\frac{1}{8}$ in. to $6\frac{1}{4}$ in., according to the nature of the wood. On the Northern Railway of France the rails are 5 in. deep, $4\frac{1}{8}$ in. wide at the side, with web $\frac{11}{16}$ in. thick, and they weigh 76 lb. per yard. The Bessemer works at Terre Noire are manufacturing the rails above described for the Lyons Railway.

FIG. 4.—67 *lb. Pennsylvania Railroad Pattern.*—This is the standard pattern on this line, for both steel and iron. Not less than 10,000 tons of steel rails from this pattern, about half of them having been made by the Pennsylvania Steel Company at Harrisburg, are in use. The shape of the head might be slightly improved for fishing, but altogether, it is an excellent pattern.

FIG. 5.—*The 56 lb. "Ashbel Welch" Rail.*—Mr. Ashbel Welch, the President and Engineer of the combined Camden and Amboy and New Jersey Companies, long ago determined to get the maximum service out of the new material. Instead of following the proportions adopted for iron, he made a pattern specially adapted to the greater strength of steel. His first pattern was still thinner in the flange than the present one, and although he expected to meet the views of rail makers a little more closely, in the end, be determined to test the capacity of steel to roll into such thin shapes, and its capacity to stand the service when rolled.—So he told the rail makers that they must make his pattern or none. John Brown & Co. at length undertook it, and found less difficulty than they had expected. The rails were put down where the service was hardest on the Camden and Amboy line, and stood perfectly. But upon the representations of rail makers that such very thin flanges would cost more—there being more "wasters"—and that they would not be as strong in proportion to their metal as thicker ones, on account of their cooling and rolling cold while the rest was hot, Mr. Welch changed the pattern to that shown in fig. 5. This is not a pattern that red short steel, or roughly cast ingots, will roll into with any success, but the Pennsylvania Steel Company have just rolled 500 tons of it for the Philadelphia, Wilmington and Baltimore line, without more than the usual number of bad flanges—in fact, without any difficulty to speak of. This is a very carefully studied and, in an engineering point of view, excellent pattern, but railway companies have thus far selected the other rail of the same weight (fig. 2) in the majority of cases.

FIG. 6.—67 *lb. Erie Steel-headed Rail.*—This is the latest Erie pattern. The Trenton Iron Company are now rolling this pattern, on an order, the extent of which we shall not undertake to mention. They are producing excellent rails with heads made either of puddled steel, or of steel made by the Siemens-Martin process.

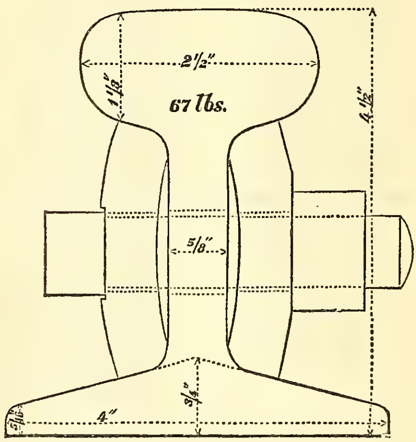

Fig. 5.

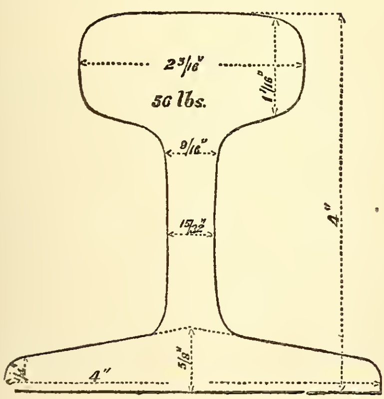

Fig. 6.

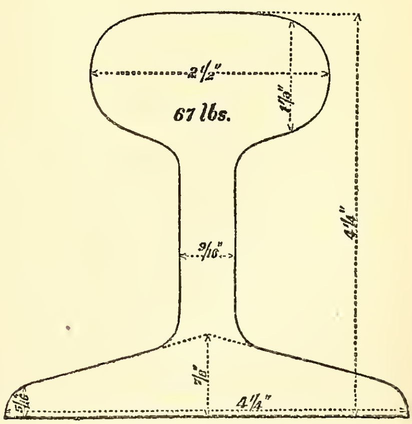

REEVES' NEW JOINT FASTENING.

Fig. 1.

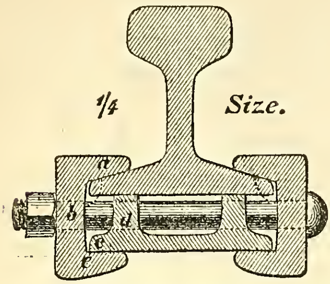

Fig. 2.

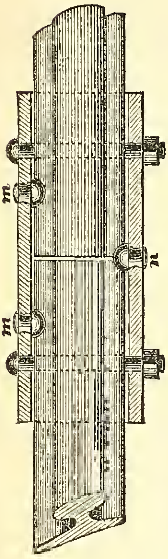

Fig. 3.

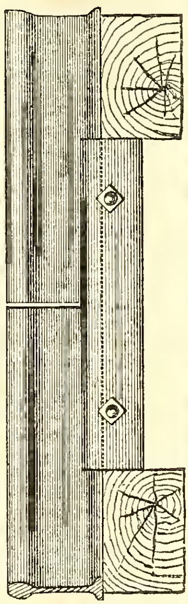


The most approved form of this excellent device, to which we have referred on other occasions, is illustrated by the above cuts. It should be explained that stops *n* and *m*, fig. 2, are not used on both sides of the rail. The single stop *n* requiring only the corner of the flange to be cut off, has been heretofore used. Mr. Reeves, however, prefers the two stops *m m*.

The advantages of this joint fastening, especially for steel rails, are very clearly set forth by the letter of Mr. Hinckley, President of the Philadelphia, Wilmington and Baltimore Railway (see page 357). The engineer of this line reports that only two nuts in the 8,000 in use have been found loose, and that only one clamp has been broken, and this by driving it with a sledge upon the rail. The motion of a train over these joints is noticed to be very smooth, and instead of the clatter observable in case of a common chair, or any loose joint, a peculiar ringing noise is heard, resembling the sound of a solid piece of metal when struck. This is the best evidence of the continuity produced by a tight joint.

The elasticity of the joint is another noticeable feature. There is nothing about it representing an anvil. The points *a*, *c*, *e*, and also the edge of the flange, may all yield very slightly. That they do so yield is proved by the fact that no wear is observed between the parts in contact. Wear always occurs between rigid parts similarly situated, as in case of the old-fashioned compound rails.

The weight of this fastening complete, with clamps 14 in. long, is 30 lbs. Its cost is $2.

The Rensselaer Polytechnic Institute—This scientific school is one of oldest, if not itself the oldest, in the country; and certainly no other American institution has furnished so many successful engineers. The course of study is very severe; and young men who graduate and receive their degrees at Troy are qualified to commence brilliant and useful careers.

It seems strange to us that for so many years, during which other institutions, no whit more deserving of support, have been munificently endowed, this one has been left entirely dependent upon the fees of the students. As a consequence those rates are comparatively high. Two hundred dollars a year is, we are informed, the present charge for tuition; and it is not found to be more than sufficient for the maintenance of an efficient system of instruction and practical training. But it undoubtedly operates to prevent many from attendance who would gladly purchase, at a lower rate, the benefits of a scientific education.

In addition to its age and general excellence, the Rensselaer Institute has two special claims upon the public. The first lies in the fact that in the destruction of its buildings by fire, a few years ago, its scientific resources were sadly crippled. It is true that indomitable energy and perseverance have done much to repair the damage. A new and handsome building upon the steep hill-side overlooking the city of Troy, and the beautiful and well-appointed Winslow laboratory close by, bear witness to the vitality which inheres in this enterprise, and give promise of its extended activity and influence in the future. The Institute is gradually replacing its lost library, apparatus and collections. It is slowly recovering from the disaster which befell it; and there is no doubt of its ultimate and complete success on a larger scale and by a higher standard than measured its ancient glory. But this recovery, however sure, ought to be quick, not slow. Whatever money can do to annihilate time should be done.

The other claim of this institution upon the public is the provision which has been made in its courses for the education of mining engineers and metallurgists. During a recent visit we were much pleased with the progress already achieved in this department, and the judicious plans matured for the future. As our readers are aware, Prof. G. W. Maynard occupies the chair of mining and metallurgy.

When it shall at last come to pass that our American, like the European mining schools, shall be distinguished, each in some special branch of the arts related to mining, we think Rensselaer will be likely to represent especially the metallurgy of iron, a branch so important as to form in some foreign schools, as, for instance, that of Losben, the chief attraction for students, and the main portion of the instruction imparted.

Troy is the site of the far-famed Burden iron furnaces and rolling mill, as well as the scarcely less celebrated Bessemer Steel Works of Messrs. John A. Griswold & Co. The latter were seriously injured—we may almost say destroyed—by fire a few months ago, but are now being rebuilt under experienced management. They can produce at present but eight tons of Bessemer steel daily; but the works now in progress will increase this capacity to upwards of fifty tons. The innumerable puddling furnaces and other iron-metallurgical works in Troy, added to the two establishments we have mentioned, are so many arguments for the importance of maintaining with ample power, in the midst of an industry so vast and profitable, an institution like the Rensselaer, to serve as a storehouse for the preservation and an exchange for the communication of a great number of valuable observations concerning the latest processes of the metallurgy of iron. Moreover some provision might be made for giving certain courses of instruction by public lectures or otherwise to the workmen themselves. Even a common laborer accomplishes all the more and all the better for understanding what he is doing.

A course of popular and scientific lectures is in progress for the aid of the Institute library. We sincerely hope it may succeed; but this is too slow a means to achieve the desired result. There is little merit in urging other men to give their money for the public good; but we think ourselves justified by the circumstances in remarking that the rich men of Troy, and all the graduates of the institution, or their friends, should unite to raise for the school a large permanent endowment. Such assistance, rendered at the right moment, *i. e.*, very soon, would have a marvelous effect in stimulating the activity and doubling the beneficent influence of the Institute. Who endows the Rensselaer school?—*American Journal of Mining.*

ENGLISH ORDNANCE EXPERIMENTS.

EFFECT OF CANNONADING A CASEMATE, UPON SHELLS STORED WITHIN IT.

From "Engineering."

On February 11th, an experiment was conducted at Shoeburyness, with the view of ascertaining the probable effect which would be produced by a cannonade upon a casemate within which loaded shells were stored, and also the extent of damage which the explosion of one shell would produce upon the surrounding ones. For this purpose 50 live common shells, for the nine in. rifled gun, were disposed with the area of an armor-plated casemate. Each of these shells contained a bursting charge of eighteen lb., in all 900 lb. of powder. The floor of the casemate is about 20 square feet, the height to the crown of the brick-turned roof being about twelve ft. The opening at the west end of the casemate was closed up by two seven in. thick iron plates, eight ft. six in. by four superficial, and weighing about five tons each. The opening at the east end was closed by several large sheets of iron $\frac{3}{4}$ in. skin and the huge rope manlet. The rears of the two casemates were left perfectly open. The main mass of the shells, 42 in number, and containing 798 lb. of powder, were laid on their sides, and piled in two rows, with their plugged ends pointing laterally outwards. For the convenience of aiming the gun through the porthole, the pile of shells was raised two ft. nine in. above the floor on a platform about eight square feet, composed of bags of sand and concrete, packing-boxes, and loose earth, covered over with an old deal target. Four shells were placed against each wall of the casemate at the side, about six ft. or seven ft. away from the pile.

The nine in. Woolwich muzzle-loading rifled gun was placed at 70 yards in front of the casemate, and laid at the center of the pile, as seen through the open port. The charge was the full battering charge of 43 lb. of large grained rifle powder, and the Palliser shell weighed, empty, 246 lb., and contained a bursting charge of five lb. twelve oz. The gun was fired by the magneto-electric apparatus, and the result of the explosion on the exterior of the casemate was to shake the massive brickwork and masonry of the casemate, to widen and increase the cracks and fissures made by the former firing against the armor, and to open new ones. Inside the structure the wreck was terrible to look at, the whole floor of the casemate being covered with the *debris* of concrete, earth, fallen bricks, fragments of wood, and exploded shells, commingled with entire shells which had not been injured, and which were thrown about in all directions, one 28 yards away on the open beach to the rear. On closer examination it was found that nineteen shells had been exploded, and that 31 had been hurled violently away without damage. Fearful, therefore, as the destruction looked, it must be remembered that the experiment was a thoroughly crucial one, and that the shells had really shown themselves as safe magazines for powder as could possibly be expected.

In the interior of the casemate itself there was first the concrete and earth platform; the floor was covered to the depth of some inches with the *debris*. Two shells lay close to the front, one on each side of the port; another on the sill of the west opening, the four which were stood erect along the rear part of the west wall being all blown aslant, and two others out of the pile lying aslant likewise, close to the wall beside them. The large iron skin (6 ft. 6 in. by 6ft. 6 in., $3\frac{3}{4}$ in.) at the back of the shield buttress, was blown down.

To the seaward, within seven ft. of the casemate, there were ten unexploded shells, one had a fragment broken from its rear end six in. in length and one in. wide. Sixteen feet seaward of this again, lay two whole shells on the west side, and at fourteen ft. one on the east side; and still farther seaward, 28 yards away from the casemate, lay the most distant of the shells cast away from the pile by the explosion. Thence to the water's edge, some 70 paces, the ground was strewed with fragments of shells and broken wood. Outside the eastern opening the two seven in. plates were blown away from six to twelve ft., two whole shells were lying among the *debris* of sand bags; 30 ft. from the casemate a third whole shell was found perfectly uninjured.

The front of the pile of shells before the firing was 21 ft. from the face of the port-hole; the quantity of powder in the shells exploded was 342 lb. The attacking shell would seem to have driven right through the two lowest tiers of piled shells, say twelve and ten respectively, and, in total, 22, exploding nineteen, and knocking the three rear ones away.

PRACTICAL INSTRUCTION IN ENGINEERING.—The engineering course at Lafayette College has some features which are worthy of the attention of all our technical schools. While the general curriculum, embracing four years, is designed to give the engineer all the culture of a thorough college course in addition to the special instruction for his profession, this class is organized as an engineering corps, and goes through all the necessary operations for the construction of a railroad from Easton to some selected terminus. This work includes reconnoissance, running preliminary lines, fixing the final location of the road with the most favorable attainable grades and curves, the construction of maps, profiles, cross sections, &c., the computation of excavation, masonry, &c. The field work and office work, including drafting and calculation, are performed under the immediate direction of Professor Walling, who accompanies the corps and directs their investigations. The bridges, tunnels and depots, are also located, and all necessary plans and calculations are made, with a discussion of the principles involved. In short, the whole work of a division engineer is performed, so that the graduate has not only scientific theory, but actual practice, and is ready at once to assume important and responsible positions.

We may add that the technical courses at Lafayette have all been recently enlarged and greatly improved. Mr. Pardee, of Hazleton, Pa., has contributed for this object the munificent sum of two hundred thousand dollars, making, with the generous donations of other friends of the institution, nearly half a million of dollars lately added to the college funds.

PAPERS ON CONSTRUCTION.
No. I.

By Lieut. C. E. Dutton.

The determination of the strength of materials involves an investigation into the following conditions: (1) the nature of the material; (2) the stress to which the various pieces are subject; (3) their shapes and dimensions; (4) the manner of their support. Although other conditions must be frequently considered, the foregoing are universal.

It is not proposed, in these papers, to discuss the more general properties of material separately, since these are in the main well understood. Particular discussions, however, in connection with other conditions will be given in the proper places.

The strains to which material is subjected may be reduced to five kinds: (1) tension, (2) compression, (3) transverse strain, (4) shearing, (5) torsion. To these might be added a sixth, viz; those internal strains resulting from the peculiar molecular constitution of the material when subject to certain forces acting upon molecules or atoms. This kind of strain, however, should more properly be considered in a discussion of the nature of materials.

1. A body is subject to a strain of *tension* when two forces are acting upon it in opposite directions, and *from* each other. A body fixed at one end, and having a tensile force applied to the other, resists rupture by the cohesive force inherent in the molecules which constitute it. It is generally assumed that, in a body nearly homogeneous, each molecule opposes to a given force a resistance nearly equal to that of every other molecule. Although this assumption is only approximately true, it is necessary to make it, since it is the only way in which we reduce the phenomena of resistance of materials to system, and subject them to analysis.

It will be safe enough to assume, whatever may be the resistance of any molecule to rupture by a given force, that their average resistance is a constant quantity. On this assumption the total resistance of a body to rupture by tension, at a given section, will be the sum of the resistances of all the molecules of that section. The number of these is directly proportional to the area of that section, and hence the resistance will always be proportional to that area.

This proposition must be qualified in particular cases by the condition that the stress be applied equally, and at the same time, to every portion of that area. In the case of a cylindrical rod, or bar, if the force be applied at the convex surface of the cylinder only, it is evident that a portion of the surface will be strained more than the central or axial portions, and the cylinder will yield to a force less than that due to the area of section, by the rupture, first, of the surface portions, and then of portions successively nearer the axis.

2. All materials under tension are elongated. The elongation becomes permanent when the tension is great, and increases in a higher ratio than the force applied. A restoration takes place when the force is removed; but it is only partial, except in cases where the force is slight compared with the ultimate strength of the material. Continuous tension, or tension repeatedly applied, even within the limits of elasticity, will produce a set, and if sufficiently continued will ultimately produce rupture, or seriously impair the strength. A slight diminution takes place in the permanent set when the body is allowed a protracted rest. Within the limits of tension to which sound practice would subject any material, it will give a closely approximate result if we make the extension proportionate to the force applied. It is also in direct ratio to the length of the piece, and in an inverse ratio to the area of section; whence the following formula: $e = \frac{t\,l}{A}m$, in which $e =$ the extension, $t =$ the strain, $l =$ the length of a piece of uniform section, $A =$ the area of that section, and $m =$ a co-efficient to be determined by experiment.

In most equations relating to the strength of materials, experimental co-efficients necessarily enter. These co-efficients are dependent for their value upon the properties of the materials under discussion, as determined by direct experiment. Thus, in an expression of the tensile strength or resistance to compression, it would indicate the tenacity or resistance per square inch: in an equation of transverse strength it may express the transverse strength of a piece of material one foot long and one inch deep. In general it may be said to express the value or amount of a particular property, found experimentally in a piece of the material under discussion having given dimensions.

For a moderate stress of tension the elongation of a bar is approximately a measure of the strain. The *modulus* of *elasticity* for extension (which is a method of expressing the resistance to extension) is determined by the amount which a bar of given size can be extended by a given weight. This resistance will evidently vary directly as the length and stress, and inversely as the extension. Let l be the length, s the stress, and e the extension; then $M=\frac{l\,s}{e}$. This expresses merely the intensity of resistance within the limit of elasticity, and does not hold good beyond it.

3. In practice it is found necessary to divide the theoretical strength of all materials by a divisor varying with the material and kind of strain, for the working strength of all materials intended for continued use is seriously affected by various causes which cannot be calculated, except as average results of experience. In tensile strains the safe load is usually estimated at from one-tenth to one-fifth the theoretical strain. The divisor is called the "*factor of safety*. Since all estimates for strains, of whatever kind, require modification by a suitable factor of safety, the relations of "breaking loads," "proof loads," and "working loads," to each other will be specially treated of hereafter.

4. *Resistance to crushing.*—Crushing is an operation of considerable complexity. In practice materials seldom yield to direct compression. It is only when pillars of considerable length are subjected to such a stress that rupture occurs, and then it is produced by flexure, and almost never by a collapse of the material itself. The strength of a column, therefore, will depend both upon its resistance to crushing and its rigidity. Mr. E. Hodgkinson, of Manchester, has investigated this subject experimentally with great ability, and his results have become standard among engineers.

Rupture by compression may take place in the following modes: (1) by splitting into laminated or prismatic fragments, like hard wood well seasoned; (2) by bulging, lateral swelling, or spreading, which is characteristic of tough, ductile material like wrought iron. In both these cases the resistance is decidedly less than the tenacity, and takes place gradually. (3) By sliding, or oblique shearing, which occurs in substances of a granular or crystalline texture like cast iron and stone. In such cases wedges or cones are forced out laterally. (4) By buckling, which takes place in beams made of flexible material, and longer than those which yield by bulging.

The formulæ obtained by Mr. Hodgkinson are as follows:

Let $D=$ the external diameter or side of square in inches.
Let $d=$ the interior diameter of hollow column in inches.
Let $l=$ the length in feet.
Let $w=$ the breaking weight in tons (2000 lbs.)

Solid cylindrical column cast iron, ... } $w=49.4\frac{D^{3.55}}{l^{1.7}}$

Hollow cylindrical column cast iron, . . } $w=49.6\frac{D^{3.55}d^{3.55}}{l^{1.7}}$

Solid cylindrical column wrought iron, . . . } $w=149.7\frac{D^{3.55}}{l^{2}}$

Solid square pillar of oak, ... } $w=12.2\frac{D^{4}}{l^{2}}$

The foregoing formulæ are for columns with flat ends whose lengths are from 30 to 60 times their diameters, and which yield wholly by bending. When the columns are shorter than these proportions, and are longer than five or six times their diameter, the rule is as follows: first, find the value of w by one of the preceding formulæ; then let $c=$ the crushing strength per square inch of the material under discussion, then breaking weight $=\frac{c}{1+.75\frac{c}{w}}$.

The following formula is deduced by Mr. Lewis Gordon from Hodgkinson's experiments for a column of *any* section.

Let $w=$ breaking weight in lbs., $a=$ sectional area in inches, $l=$ length, $d=$ the least external diameter, $c=$ a constant dependent upon the crushing strength per sq. in. of the material, $e=$ a constant dependent upon resistance to flexure; then, approximately, $w=\frac{c\,a}{1+e\left(\frac{l}{d}\right)^2}$.

The following are the values of c and e for iron pillars having flat ends:

	Values of e.
Wrought iron.	$\frac{1}{3000}$
Cast iron.	$\frac{1}{400}$

Values of c.	Breaking load.	Proof load.	Working load.
Wrought iron.	36,000	18,000	6,000 to 9,000
Cast iron.	80,000	26,700	13,300 to 20,000

In using the foregoing formula it will be necessary to use care in determining the ratio $\frac{l}{d}$. In wrought iron frame-work and machinery the bars which act as struts, in order that they may have sufficient stiffness, are made of various forms in cross section, well known as "angle iron," "channel iron," "T-iron," and "double T-iron," etc. In each of these forms the line to be considered as d is the diameter in that direction in which the bar is most flexible, of a triangle or rectangle circumscribed about its section.

The ultimate resistance of wrought iron tubes, composed of plate iron riveted to angle irons at the corners, was stated by Mr. Fairbains to be 27,000 lbs. per square inch of section of iron. This is in cases where the ratio of length to diameter exceeds 30. The yielding is always by buckling. But when a number of these tubes are placed side by side, the resistance becomes 33,000 or 36,000 lbs. The same co-efficients apply also to cylindrical tubes. (Rankine.)

5. In cases where the center of pressure does not coincide with the axis of the column, it is evident that a greater strain will be thrown on one side than on the other, and the load which the column will sustain will therefore be diminished in the ratio in which the mean intensity of the stress is less than the maximum intensity. To find that ratio it is sufficiently near the truth to assume that the stress is uniformly varying.

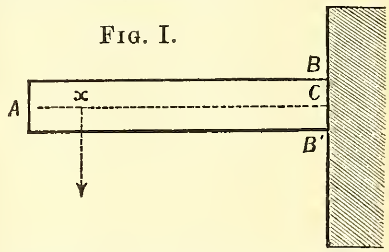
Let $x =$ the greatest deviation of the center of pressure from the center of figure in any cross section; that is, the greatest deviation of the line of action of the load from the axis of the pillar. Let x' be the distance of the point of greatest stress from the axis of the pillar; that is, the same diameter of the pillar in the direction in which the load deviates from the axis.

Let I denote what is called the moment of inertia of the cross section of the pillar (a term which will be explained under the head of transverse strength); let $S =$ the area of the transverse section in sq. inches, and let $f =$ the resistance of the material to crushing in lbs. on the sq. inch. Then the crushing load is $P = \dfrac{f\,S}{1 + \dfrac{xx'S}{I}}$. The following are some of the values of $\frac{x'S}{I}$ in this formula. (Rankine.)

I. Rectangle $h\,b$; b neutral axis, ...	$\frac{6}{h}$
II. Square h^2	$\frac{6}{h}$
III. Ellipse; neutral axis b; other axis h, . . .	$\frac{8}{h}$
IV. Circle; diameter h, .	$\frac{8}{h}$
V. Hollow rectangle outside diameter $h\,b$; inside diam. $h'\,b'$; neutral axis b, ...	$\frac{6\,h\,(h\,b - h'b')}{h^3\,b - h'^3\,b'}$
VI. Hollow square $h^2 - h'^2$	$\frac{6\,h}{h^2 + h'^2}$
VII. Circular ring diameters h and h', . . .	$\frac{8\,h}{h^2 + h'^2}$

6. *Transverse Strength.*—A horizontal beam having one end fixed in a vertical wall, and subjected to stress in a direction perpendicular to its length, will be forced out of its normal shape and subjected to internal strains of a complex nature. If a weight act vertically downwards, the upper layers of the beam will be subjected to tension, and the lower layers to compression. There will be an intermediate layer where neither of these forces operates, and this is called the "*Neutral Axis.*"

Fig. I.



It is plain that the greatest tension occurs at the upper surface, and the greatest compression at the lower surface, and the amount of change in any layer is proportional to the distance of that layer from the neutral axis. The effect produced upon the beam by a given weight will obviously vary directly as the distance from the wall at which it is applied. If $A\,C$, Fig. I, be the neutral axis, then $A\,C\,B$ and $A\,C\,B'$ may be regarded as bent levers of which the arms $C\,B$ and $C\,B'$ are constant; and if the weight W be applied at the distance x, then the effect of W will vary as x. If W be multiplied by the distance at which it acts, the product will be what is called the "*Moment of the Weight;*" *i. e.*, the amount and efficiency of the force as determined by its "*leverage.*" When the weight is applied at a single point, then the moment of weight

$= Wx$. When it is distributed over a continuous length, it is plain that each point has a moment of its own, and that the whole moment will be equal to the sum of the moments of all the parts. Suppose the beam to be divided up into an indefinite number of equal parts, having the length dx; then the weight on each of these parts will be proportional to the length of the part, and equal to the intensity of the weight multiplied by this length. The intensity of weight for a unit of length is equal to the whole weight divided by the whole distance over which it is distributed, and in case the beam is uniformly loaded over its whole length, the intensity will be $\frac{W}{l}$ and the weight upon $dx = \frac{W\,dx}{l}$. The moment of this weight will be $\frac{W}{l}.x\,dx$, in which expression $\frac{W}{l}$ is a constant quantity. The entire moment therefore (making $x = l$) is

$$M=\frac{W}{l}\int x\,dx=\frac{W}{2\,l}\cdot\frac{1}{2}x^2=\frac{W^3 l}{2}.$$

The moment of a uniformly distributed load is therefore one-half the moment of the same load acting at the free end. In case the load is uniformly distributed over a part of the length $= a$ between the points x and x', the above expression becomes

$$M=\frac{W}{a}\int_{x'}^{x} x\,dx=\frac{W}{a}\tfrac{1}{2}\left(x^2-x'^2\right).$$

Making $x = l$ and $x' = l-a$ the above becomes

$$M=\frac{W}{a}\tfrac{1}{2}\left(l^2-(l-a)^2\right)=W\left(l-\frac{a}{2}\right).$$

7. When a beam is supported at both ends, and a weight applied between the supports, we may consider the reaction of these supports as forces acting upwards upon the free ends of a beam supported in the middle; or the beam may be considered as a lever of the third order, where the power is applied between the extremities. Adopting for the present the latter view, and making $l =$ the distance between supports, and $x =$ the distance from A of the point of application of the weight, then the pressure upon B, or what is the same thing, the reaction of B will be inversely as the length, and

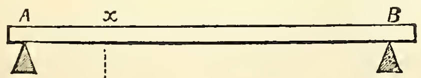


Fig. II.

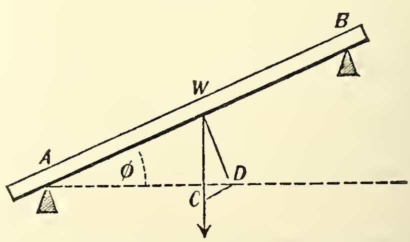
directly as the weight, and the distance from A; *i. e.*, $P=\frac{Wx}{l}$. Similarly, the pressure upon A will be inversely as the length, and directly as the weight, and the distance from B; *i.e.*, $P'=\frac{W(l-x)}{l}$. Adding these equations $P+P'=\frac{Wx}{l}+\frac{W(l-x)}{l}=W$, we find that the sum of the pressures upon the two supports is equal to the whole weight. The moment of reaction of the support B will be $=P(x-l)=\frac{Wx\,(l-x)}{l}$ and the moment of reaction of the support A also $=P'x=\frac{W(l-x)\,x}{l}$: therefore these two moments are always equal. Since, in every case $x+(l-x)=l$, the equation of moment becomes a maximum when $x=\frac{l}{2}$, and becomes zero when $x=o$, or $x=l$. Hence the moments of weight are greatest when the weight is in the middle of the beam, and are nothing when it is at either support. Making $x=\frac{l}{2}$, then $\frac{Wx\,(l-x)}{l}=\frac{1}{4}\,W\,l$, *i. e.*, the effect of a weight placed in the middle of a beam supported at both ends is one-fourth the effect of the same weight at the free end of a beam fixed at one end.

In the case of a uniformly distributed load we may assume the supports to be forces acting upwards against a beam supported at the center by the weight. By referring to equation (1) it will be seen (bearing in mind that $x=\frac{1}{2}\,l$) that $M=\frac{1}{2}P\,(l-x)$ $=\frac{\frac{1}{2}\,Wx\,(l-x)}{l}=\frac{1}{8}\,Wl$. Hence, a beam will support twice as great a load distributed uniformly as it will when the load acts at the center alone.

8. When the weight does not act perpendicularly to the length of the beam, the foregoing conditions are somewhat modified.

Fig. III.

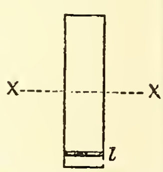


Let $A\,B$ represent a beam—its axis making with the horizon an angle $=\phi$. Let the weight act vertically, and let $W C$ represent the magnitude of the weight. Resolve $W C$ into two components, $W D$ and $D C$; the former perpendicular and the latter parallel to the axis of the beam. Then $D C$ is a force having no transverse effect, but is subject to the laws of longitudinal stress, while the component $W D$ represents the whole of the transverse effect of W. The relation of $W D$ to the whole load is expressed by the equation $W D = W \cos. \phi$, and the equation of moment becomes $M = \frac{W x (l-x) \cos. \phi}{l}$.

9. From the foregoing, therefore, we may deduce *the general principle, applicable to all cases of transverse strain, that the effect of a load upon a beam varies directly as the length of the beam.* It now remains to determine the relations of the load to the cross section. Reverting to Fig. I, it is apparent, assuming that $A\ C\ B$ and $A\ C\ B'$ are bent levers, that the intensity or effect of the resistance of any layer to extension or compression must vary as its distance from the neutral axis, because the leverage is proportional to that distance. But owing to the curvature of the beam the tendency to rupture or the strain is also directly proportional to that distance. These two forces are always equal and in opposition, up to the limit of elasticity either for compression or extension, and therefore hold the beam in stable equilibrium. Beyond that limit the action of these forces follows no known law. Our discussion, therefore, must be with reference to strains within that limit.

Let Fig. III represent the cross section of a rectangular beam, of which XX' is the neutral axis. Let l be any layer of very small thickness at the distance x from the neutral axis. Let t be the thickness of the layer, and s the intensity of the stress to which it is subjected. Let b = the breadth of the beam. Since the intensity of the stress varies directly as its distance from the neutral axis, then $\frac{s}{x} = c$, a constant quantity. The amount of stress on the layer l will be expressed thus: $Q = s\ b\ t = c\ x\ b\ t$. If we assume l to be at the edge or surface of the beam, and divide the distance between it and the neutral axis into an indefinite number of layers of the thickness t, then the amount of stress on each layer may be expressed in the same way as that on l.

Fig. III.



Thus the amount of stress on the layer next to l will be $Q' = s'\ b\ t$, and on the next, $Q'' = s''\ b\ t$. The moments of these stresses, *i. e.*, the amounts multiplied by the distances from the neutral axis, will be $s\ b\ t\ x$, $s'\ b\ t\ (x-t)$, $s''\ b\ t\ (x-2)$, etc., and their sum will be equal to the moment of resistance of the entire portion of section under discussion.

$$R = b\,t\{s\,x + s'(x-1) + s''(x-2) + s'''(x-3) \ldots\ldots\ldots + s^n\,(x-n)\}.$$

Now, $s = c\,x$, $s' = c(x-t)$, $s'' = c(x-2'')$ etc., and $t = \frac{x}{n}$ substituting these values in the foregoing equation

$$R = c\,b\,\frac{x}{n}\left\{x^2 + \left(x - \frac{x}{n}\right)^2 + \left(x - \frac{2\,x}{n}\right)^2 + \left(x - \frac{3\,x}{n}\right)^2 \ldots\ldots\ldots + \left(x - \frac{n\,x}{n}\right)^2\right\} =$$

$$c\,b\frac{x^3}{n}\left\{1 + \left(\frac{n-1}{n}\right)^2 + \left(\frac{n-2}{n}\right)^2 + \left(\frac{n-3}{n}\right)^2 \ldots\ldots\ldots + \left(\frac{n-n}{n}\right)^2\right\}.$$

The sum of the series contained in the brackets $= \frac{n}{3}$ therefore $R = c\,b\frac{x^3}{n} \times \frac{n}{3} = \frac{1}{3}\,c\ b\ x^3$.

Substituting for c its value $= \frac{s}{x}$

$$R = \frac{s}{x} \times \frac{b\,x^3}{3} = \tfrac{1}{3}\,s\,b\,x^2. \qquad (1)$$

Hence the resistance of a beam varies as the square of the depth.

The same result is obtained by direct integration, thus: making $t = dx$, then the moment of stress upon the differential layer $l = \ s\ b\ x\ d\ x = \frac{s}{x'} b\,x^2\,d\,x$. Then, since $\frac{s}{x'}$ is a constant, the whole moment of resistance becomes $= \frac{s}{x'}\int_o^{x'} b\,x^2\,d\,x = \frac{s}{x'} \times \frac{1}{3}\,b\,x^3$. Making $x' = x$ we have the same result as before.

The factor $\frac{1}{3}\,b\,x^3$ is termed the "moment of inertia" of the cross section. It is compounded of three factors, expressing as many relations: first, the intensity of resistance made by any particle of the section to a stress, which intensity varies directly as the distance from the neutral axis; second, the area, $b\ x$ of the section, or the number of particles which resist, and third, the distance or moment proper from the neutral axis at which the force acts. The factor s is termed the *modulus of rupture*, of working load, or of proof load, according as the one or other of these stresses is in question. Its value must be determined experimentally in beams of each kind of material, and in general does not correspond exactly either to the modulus of rupture for tension or for compression, but has a special value peculiar to transverse stresses.

The foregoing applies to beams of rectangular section; for beams of any other form the expression must be correspondingly modified. The analysis given has been with respect to one side of the neutral axis. An equal amount of resistance of an opposite kind takes place on the other side. So long as s does not exceed the limit of elasticity, either for the compression or extension of the material, the moments on both sides the neutral axis will be equal, and we may assume that this axis passes through the center of gravity of the section. In the rectangular section, making $d = 2x$ the depth of the beam, and substituting, we have $R = \frac{s}{3x} . b x^3 = \frac{1}{6} s b d^2$, and the moment of inertia becomes $\frac{1}{12} b d^3$.

10. In deducing from the foregoing the resistance of a beam having some other section, let $m =$ a factor depending upon the form of that section. Then the equation of resistance becomes $R = \frac{1}{6} m s b d^2$. The following table gives the values of m for several forms.

Form of Section.	$m =$
Circle $D =$ diam........	$\frac{6}{32}\pi = 0.5892$
Ellipse	the same.
Hollow rectangle $b d - b' d'$	$1 - \frac{b' d'^3}{b d^3}$
Hollow circle...........	$\frac{6}{32}\pi \left(1 - \frac{d'^4}{d^4}\right)$
Hollow ellipse..........	$\frac{6}{32}\pi \left(1 - \frac{b' d'^3}{b d^3}\right)$
Isosceles triangle base $= d$...	$\frac{1}{4}$
I section where $b' =$ sum of the depths of channels..	same as hollow rectangle

11. Hence we draw the conclusion that the transverse resistance of a beam varies as the square of the depth. Having shown already that the resistance varies inversely as the length, it remains to consider the effect of the breadth. It is plain that if we divide a beam by a vertical plane parallel to the axis, the strength will be in no wise affected; the combined resistance of the sections being equal to that of the undivided beam. Therefore the beam will vary as the number of elementary sections into which we may conceive it to be divided, or, in other words, will vary directly as its breadth.

12. The strength also will be modified by the kind of material and its properties with reference particularly to its resistance to direct tension or crushing. If the resistance of the material to tension is greater than to compression, it will yield transversely by the buckling or collapse of the compressed surface. This is the case with wrought iron or wood. If the resistance to direct compression is greater, the yielding will be by the rupture of the extended or convex surface. In computing the effect, therefore, of the peculiar nature of any material, it will be necessary to ascertain, first, whether its tensile or compressive strength is the greater, and to assume the less of the two as the true strength. Knowing the modulus of rupture for direct tension and compression, we would be able to compute readily a theoretical transverse strength of a beam of given dimensions and material. Practically, however, such a computation would be in many cases valueless, because no material is perfectly homogeneous and free from internal strains, which are beyond the reach of mathematical investigation. A lack of homogeneity may not interfere with tolerably uniform results in experiments made upon the tensile strength of materials, because such defects are generally averaged throughout a mass, and the strain at every point is uniform. But the tension developed by a transverse stress is not uniform, but varies as its distance from the neutral axis, and a want of homogeneity in the extreme outer layer is sure to make itself apparent by yielding at the point where it is weakest. The use, therefore, of the constants which would be furnished by the moduli of elasticity is inadmissible. A much more reliable method, as already intimated, is to determine the resistance of beams of standard size to transverse stress for each kind of material, and adopt the results as co-efficients.

Nor is this the only error to which such a computation would be liable. It is found in practice that the value of a constant depending upon the nature of the material, is constant only for a given form of cross section. The same material, in beams of different cross sections, will offer an amount of resistance which cannot be accounted for by the known relations of form to theoretical strength. It becomes necessary then to determine experimentally the value of each kind of material in beams of various cross sections before we can obtain an empirical constant which is to be depended on. Any other method of arriving at such values is always liable to a very material error.

Representing by m the value of this experimental constant, and having already determined the relations of the three dimensions—length, breadth and depth—we may now proceed to deduce general expressions for the relations of the load to the dimensions of the beam, within the limits of elasticity. In all cases the resistance, R must be equal to the tendency to rupture, N; and the expression

$$N = R$$

must be true for all possible values and conditions. But it has already been shown that the stress or tendency to rupture is equal to the moment of the weight $N = Wx = Wnl$ (n being a constant dependent upon the position and distribution of the load), and the resistance is a compound of the breadth, the square of the depth, and the experimental constant m, $R = m\,b\,d^2$. Hence

$$W n l = m\,b\,d^1.$$

Excellent tables, from which the values of m may be deduced will be found in the "Engineers' and Mechanics' Pocket Book," by Charles H. Haswell, Esq.

(To be continued.)

IMPROVED WORKING OF STONE QUARRIES.

By M. Camille Trougnoy. Translated from "Annales du Génie Civil" for "The Engineer."

We saw some months ago a granite quarry worked, at Beauvais-les-Rochers (for paving stone) with a powerful machine, invented by M. Joanne Ronceroy, which completely supplants powder and yet allows of the granite being detached in blocks and broken up almost without waste. The principal part of this machine is a monkey (drop) of 800 kilogrammes, carried with two iron rods which guide it in its fall, on a carriage which turns on the arm of a crane. This arm is horizontal, its jib is 12.50 metres in length, and about eight meters above the ground level. It is the fall of the monkey which detaches the blocks. A chain worked by a windlass raises the monkey when it has fallen, and nippers detach it when raised. The monkey is a mass of cast iron with two ears placed laterally on it, through which pass the guiding rods, and two more on the upper part by means of which the rope is fastened which, with the assistance of a pulley, serves to hang it on the raising chain carrying the nippers. The monkey is pierced by a hole opening into a cavity which receives a mass of iron (a die) on the lower surface of the monkey and which gives the blows. The object of the hole is to enable the die to be removed when worn. The guiding rods are round bars of iron twelve to fourteen meters long and six to eight centimeters diameter. They are kept at the same distance apart by a plate on the turning carriage, which has two holes bored in it of greater diameter than the rods. The lower part of the rods is fastened and kept at a fixed distance apart by a short iron strap, carrying two wooden blocks which can oscillate in the strap. Between the two blocks is left a free space through which the monkey can pass. The blocks of wood serve to deaden the shock after the blow has been struck on the stone to be detached. Finally, at each end the strap is provided with two pulleys, on which run two chains to raise and lower the rods at will. These chains work on a second windlass, independent of the one which belongs to the monkey. The carriage is like that used for the cranes of stores, and is worked by a chain from a third windlass. The arm of the crane is formed by joining two beams in the shape of a double T made of sheet and and T-iron, between which rolls the carriage. The complete machine carries three arms identically the same and symmetrically placed. The vertical shaft is borne on a large truck moving on rails, the surface of which is a square of five meters. On this platform is placed a horse-gin, to which the vertical axis serves as an axis of rotation. The horse-gin is hidden by vertical sides forming an enclosure, in which moves the horse which works the horse-gin. By means of a lever the different windlasses can be placed in connection with the horse-gin. Besides, the dispositions are such as that it is possible to give a rotary motion to the vertical axis to which the arms are attached, without displacing the platform of the horse-gin above the point on which it is to act. All the windlasses are placed on a second platform forming a kind of turn-table, placed high enough for the horse to pass under it, and on it stands the man attending to the working of the apparatus. Under the large platform of the carriage is placed a mechanism which is attached to the horse-gin, and which, by means of a chain, draws backwards or forwards the whole system, which moves on rails.

The machine is used as follows: The upper part of the ground is levelled; a line five meters wide is laid perpendicularly to the face of the rock to be cut and five or six meters back; the machine is placed on this line. A man stands on the upper platform, and turns the apparatus so that one of the arms of the crane shall be about over a cutting previously made in the soil to admit a wedge which will serve to detach the mass; the carriage is then advanced or drawn back sufficiently so that the strap of the two guiding rods being lowered, the wedge can pass between the two wooden blocks; these blocks are carefully wedged with waste stone, so that they lie firmly on the stone, which they can do from the slight oscillatory motion they can take. The monkey is then raised to the required height to detach with a single blow the block of granite corresponding to the position of the wedge. The nippers are loosened, and the monkey detaches a block of from five to ten cubic meters. The placing in position of the apparatus and detaching of the block takes five minutes. Enough men must be employed to prepare the places of the wedges, either in the blocks to be detached or in those already detached, which are to be broken up. Each hole for a wedge in the granite takes an hour to make. The inventor states that twelve workmen, each having a man to help him, would be required, also a man to guide the machine, and five men to move and load, in all 30 men. The machine itself can assist in loading the blocks, as it is a regular crane. For breaking up small blocks, a special machine, which reminds one of a pile-driver is used, only the monkey, which is comparatively light, has a projecting cutter on its lower surface, and which is perpendicular to another cutter on a fixed cast iron anvil. The top of this anvil is surrounded by a framework, into which is put granite dust to the level of the cutter on the anvil; on this dust the block to be broken is placed and kept in position by means of a stiff wooden bar. It appears that considerable saving results from these two machines. They possess the advantage of not being liable to get out of order like that which has been used in the environs of Fontainebleau, and which necessitates the use of a steam engine—a kind requiring men accustomed to the management of steam-engines. It must, however, be admitted that this machine is very cumbrous, and one would like to know whether, by adopting the principle of the use of very heavy masses, for cutting rocks, a means could not be discovered which would permit of its application in the earthworks in the limestone and granite strata which will be met with in great numbers on the railways authorized in 1868.

Engineering Architecture, says President Haughton, in his address before the Mechanical Engineers, is a subject which the Society would do well to keep continually before it, because it is a line in which we can see our way, and in which every one admits there is room for improvement; it is, indeed, humiliating to think of the vast sums that have been spent in England on grand engineering works, with an utter disregard of appearances. and where a modicum of æsthetic skill would have given us so much effect and beauty. It will be said that utility and not beauty should be the cry of the engineer; but this is, after all, only the twaddle of incompetency, for it is well known to those who have given attention to art, that it costs no more to arrange materials in effective and pleasing forms, than to pile them in the shapeless masses that attract the eye. We must at once dismiss the assertion that beauty is costly; it is not meretricious ornament that is advocated, such as may be seen in at least one of the latest engineering works.

What I ask you to aspire after in those engineering works upon which you are engaged, is form, in the æsthetic sense, in place of that deformity which is sown broadcast around us, in which the British engineer has hitherto glorified himself, and in which he would seem to wish to idealize and deify sheer strength, which in his simplicity he sees to be incompatible with beauty of outline. Let the engineer above all things refuse to entertain the thought that veneration for the beautiful is beneath him as a man, or derogatory to the dignity and character of his race; for during all times those races which made themselves famous for their prowess and their majesty, their power alike over matter and mind, were equally renowned for the beauty and for the magnificence of their public works—those monuments of glory by which, history apart, we can now alone judge of their aristocracy of race.

HEATING AND VENTILATION.

Compiled from the late report of Alban C. Stimers, Esq., on the Ventilation of the Hall of the U. S. House of Representatives.

The term ventilation when applied to a hall of this importance should signify the production and maintenance within doors of pure air, properly tempered with heat and moisture, regardless of the existing state of the weather. A consideration of the subject is therefore properly divisible into the following heads:

1. The quantity of air necessary and how it should be introduced.

2. Warming and moistening the air in cold weather.

3. Cooling and drying the air in hot weather.

The subject of regulating the degree of moisture in the air when it is neither warmed nor cooled, is naturally involved in the above.

THE AIR SUPPLY.—A cubic foot of air at a temperature of 65° with the dew-point at 52° will absorb $2\frac{1}{2}$ grains of vapor. Each person exhales 15 grains of vapor per minute, and also requires $\frac{1}{4}$ cubic foot for breathing, $=6\frac{1}{4}$ cubic feet of air vitiated by each person per minute.

In supplying air for the ventilation of such a hall, it is absolutely essential that the direction of the current should be vertical; otherwise that which has been vitiated by one person will be given to another. If this envelope of vitiated air be drawn upward, the nose and mouth will be always supplied with it, no matter how pure the air may be one foot away; while, if it is drawn downward, those organs will always be supplied with pure air. The temperature of the human body rarely varies 2° either way from 98°. If, therefore, the air is supplied at a temperature of 65°, it will be 32° cooler than the body; with the downward current the head will be in this cool air, while the feet will be enclosed in an atmosphere nearly if not quite as warm as the blood within them. And to "keep the head cool and the feet warm" is one of the fundamental rules of hygiene as well as of comfort. A current of air coming up through the floor will always carry the fine dust which the greatest care cannot prevent accumulating. With downward ventilation it is only necessary that the dust shall be thoroughly removed from the inflowing air at the mouth of the inlet to keep the hall free from dust. Again: with upward ventilation, the entire hall is filled with vitiated air, the vitiation having taken place near the point of admission; while with downward ventilation the vitiation takes place near the point of exit, and the whole upper part is full of pure air.

During the downward movement of the body of air in a high room, all eddying currents, induced by the increased velocity through the apertures, become quiet, and the whole mass descends with a uniformity impossible to obtain in the vicinity of the persons ventilated with upward currents; and one of the most important considerations to be kept in view in ventilating an apartment is to avoid perceptible draughts. The only limit to the amount of air that can be advantageously supplied, is the avoidance of sensible currents. Most people can feel a current having a velocity of 150 ft. per minute; very few can perceive one of 90 ft. The maximum velocity proposed in this case is 50 ft., and the hall being $139\frac{1}{3} \times 93$ ft. in plan, the quantity of air required would be 647,900 cubic feet per minute.

The first method adopted by engineers and architects to give movement to air, for the ventilation of mines and buildings, was to heat an upflowing column, thus lessening its specific gravity and causing it to rise with corresponding force. That system is still employed in the British houses of Parliament. It has been practically demonstrated, however, that one pound of coal burned in the furnace of a steam boiler, which furnishes steam to drive a fan blower, will generate as much force, and consequently is capable of producing as strong a current of air, as 38 pounds expended in heating a column of air to act by its diminished gravity. English engineers commenced about ten years ago to apply fan blowers to the ventilation of mines. The French had previously adopted this practice. In addition to the economy of this method, the complete control which the attendant is enabled to maintain over the quantity of air supplied at all times, is found to be of great advantage.

To propel the air into this hall it is proposed to place four fan blowers, having a capacity of 200,000 cubic feet per minute each, in the cellar; thence the air passes up through shafts to the chamber above the ceiling. Here would be placed an additional ceiling of plate glass and iron, of double thickness, that it might be a non-conductor of heat, and above this the gas burners. The air would thus be thoroughly distributed over the ceiling before passing into the hall. Such openings through the present ceiling would be provided, that its present ornamental appearance would not be changed, and an equal area of opening would be obtained in each of the 165 squares into which it is divided. To insure the continuance of the air thus admitted, in a direct vertical line down to the floor there would be frequent openings throughout their extent, which should communicate to the air-chamber beneath the floor. The air from this chamber would be withdrawn by means of four fan-blowers of equal dimensions with those employed to drive the air in. From the blowers the air passes up through a separate duct, by the side of the pure air duct already mentioned, and goes off through the roof.—All these blowers would be driven by one pair of engines of 750 h. p., through the medium of appropriate gearing, shafts and belts. In every case of gearing there would be wooden teeth working into a cut metal gear, which, may be made to run with perfect silence, and is more durable than metal gearing. By running all the blowers from one engine, a uniform relation of the forces employed in different localities is secured.

Merely forcing fresh air in, would drive the foul air out, but this would mostly occur through the nearest and easiest passages, so that the fresh air would not be properly distributed. Simply drawing air out would cause in-currents from all doors and windows as well as from the intended supply duct. Excess of either induction or withdrawing forces would tend to produce these respective results. The only perfect distribution of the air will result from having the filling and exhausting forces the same.

The present place of admitting the air, near the ground, is very objectionable. Even admission by high towers would not secure air free from dust. The plan here proposed is to sink a shaft 25 ft. in diameter, some 200 ft. west of the building, in a small grove. Over it would be erected a substantial screen, 22 feet in height, and similar in form to the Capitol dome. It would be made of $\frac{1}{4}$ wire of pure block tin, that it might be durable and always clean. The meshes would be about $1\frac{1}{4}$ inch. Over the top of this there would be a revolving fountain with four jets, which would project downward, throw small streams of water with force upon the wire work of the screen, and keep every wire covered with an envelope of clean water, against which the entering air would have to rub in passing in. This forcible contact would transfer the dust from the air to the water. The muddy water would fall to the bottom of the duct and pass away by the drain through a trap. From the bottom of this vertical opening a tunnel 15 ft. in diameter would extend horizontally to the blowers in the cellar so enclosed as to draw their air wholly from this source. The tunnel is 15 feet in diameter, and the top of it passes 16 feet below the lowest point of the foundations of the building.

Warming the Air in Cold Weather.—There are three methods in common use for warming air; by passing it over, 1st, iron surfaces heated directly by fire; 2d, iron pipes filled with steam; and 3d, iron pipes filled with hot water. The first method is considered highly objectionable in first class buildings. When air is brought in contact with highly heated iron surfaces, especially rusty surfaces, an unpleasant odor and feeling are imparted to it, from the decomposition of those ammoniacal matters which are always found more or less in the atmosphere, and from its extreme dryness. Zinc surfaces are a great improvement over iron, in this respect, but block tin is considered the best material, as it resists atmospheric influences better than any other of the useful metals.

The means here recommended are pure block tin tubes filled with hot water, each tube being 10 feet long by $1\frac{1}{8}$ inches outside diameter and secured into brass tube-heads in the same manner as in the surface condenser of a marine engine. They open at each end into steam-tight chambers; into the upper chamber steam from the boilers is introduced, and from the lower one water is drawn off by appropriate pipes. It will be understood that with this arrangement the apparatus may be a steam heater, or, if the surface is enlarged enough to warm the air with hot water, the steam will be condensed in the upper chambers, hot water filling the bottom of the tubes and the lower chambers. A valve in the pipe through which the water flows away would control the rapidity with which it was drawn off and consequently its temperature. In ordinarily cold weather this would be a hot water warming apparatus, but upon any extremely cold day it would become a steam heating apparatus as the attendant opened the regulating valve in the drain pipe.

Moistening the Air.—The water thrown off by the human body, evaporates in the surrounding air. The rapidity of this evaporation is dependent entirely upon how far the condition of the air in regard to moisture is removed from the point of saturation. In ease the evaporation from our bodies is too rapid, the skin becomes too dry, and this again induees too rapid a flow of the water within the system toward the surfaee, making us uncomfortable, and sometimes ill. Evaporation is also a cooling proeess. This is explained by the absorption of the latent heat which occurs upon the eonversion of a liquid into a vapor. On the other hand, if the evaporation is too sluggish, the flow of water toward the surface is retarded and we are made uneomfortable and sometimes ill in another way; also, if the air is of the proper temperature, we are uneomfortably warm, the general feeling being described by the term "muggy." It is highly important, therefore, that the proper moisture of the air should be maintained in any system of ventilation.

An authority on this subject* says: "Air changed in temperature by warming, *without increased moisture*, produees unpleasant sensations in the head and ehest, etc. The objection lies against heated air, no matter how heated. The only way that hot air can be made healthful is by an effectual plan of artificial evaporation." Professor Henry says on this subject: "The heating af the air and preserving it at the desired temperature is the simplest part of the problem; to remove the impure air and to supply its place with fresh air, without giving rise to unpleasant eurrents and unequal temperature is more diffieult; to supply the proper quantity of moisture and to prevent its eondensation is attended with still greater diffieulty, particularly when apartments containing a large number of persons are to be thoroughly ventilated. This part of the general problem is, in my opinion, an essential element of proper ventilation, although it has hitherto reeeived eomparatively but little attention in this eountry."

Mr. Stimers' plan for moistening the air is by placing in the air duet, a system of water pipes, 10 in number, each 20 feet long, lying horizontally, lengthwise of the duet, and distributed throughout its cross seetion so as to equally divide it up. In each of these pipes there would be a great number of minute holes extending all around the cireumference and throughout the length. The water driven into these pipes with forec would spin out of these holes radially from each pipe, filling the entire duct with a fine shower.

*Dr. Youmans Hand-book of Social Science.

The "relative humidity" of the air is the percentum which the amount of moisture in the air is, of that necessary to saturate it at the same temperature. A relative humidity of 65, with a temperature of 65°, is assumed; this corresponds with

$4\frac{1}{2}$ grains of water per cubic foot of air.
A tension of 0.4 in. of mereury.
A depth of $5\frac{1}{2}$ in. of water on the earth.
A break between the wet and dry bulb thermometers of $5\frac{1}{2}$°, and
A dew point of 52°.

The lowest degree of humidity of the external air of Washington, as reported by Dr. Wetherell, was 1.11 grains per eubie foot. Assuming one grain for the base of ealculation, there will have to be added $3\frac{1}{2}$ grains per eubie foot to give it a relative humidity of 65 when at a temperature of 65°, and as there are 7,000 troy grains in one pound avoirdupois, 80,000 eubie feet of air will require $\frac{80{,}000 \times 3\frac{1}{2}}{7{,}000} = 40$ pounds of water per minute.

The temperature of the water would probably be about 40°. This would have to be warmed to 65°, and be supplied with the latent heat necessary to form it into vapor at that temperature.

To aseertain how much the air must be superheated for this purpose—

Let s = specifie heat of air as eompared with water .... = 0.2669
v = volume of air in eubie feet.... = 80,000
w = weight of air in lbs. per e. ft.. = 0.075
t = temperature from which water is raised.................. = 40°
t' = temperature to which water is raised .... = 65°
l = latent heat of steam at that temperature............... = 1070°
W = weight of water to be absorbed in pounds................. = 40
x = number of degrees the air must be heated above 65°, in order that it may be at that temperature after it has dissolved the moisture.

$$\text{Then } \frac{W\,(l + t' - t)}{svw} = x = 27°.$$

The temperature to which the air must be raised, under the above conditions of the weather, before it is moistened, would therefore, be—

$$65° + 27° = 92°.$$

To determine the extent of surfaee required for the warming tubes—

Let P = temperature of water in tubes = 192°
T = temperature of air after heating...................... = 92°

Let t = temperature of external air.. = 20°
C = volume of air in cubic feet... = 80,000
S = surface of tubes in square feet.

$$\text{Then } .0045\, C\, \frac{(P-t)\,(T-t)}{P-T} = S$$

and $S = 44{,}582$ square feet.

Each tube being 10 feet long by $1\frac{1}{8}$ inch diameter, would have a surface of 2.9 square feet. There would, therefore, be required 15,373 tubes. These are divided into eight several congeries, for convenience of construction, with 1,922 tubes in each. It is proposed to arrange indicators in the engine room, so that the engineer would always know the exact temperature and moisture in the hall, and could regulate the heat and water accordingly.

Cooling and Drying the Air in Hot Weather.—An attempt has been made to cool the air of this hall with ice. Some two tons of ice were melted in the air-duct during each day of about five hours, say 800 pounds per hour. The quantity of air passing through the duct, per minute, was 24,300 cubic feet.

The temperature of the ice was, say .... 25°
That of the water of condensation was, say, 60°
The latent heat of the ice is .... 140°

To determine how much the air would be cooled by melting the ice—

Let t = temperature of the ice....... = 25°
t' = temperature of the water of condensation .... = 60°
l = latent heat of ice............ = 140°
s = specific heat of air .... = .2669
w = weight of air per cubic foot.. = .075
v = volume of air in cubic feet... = 24,300
W = weight of ice melted per min., = $13\frac{1}{3}$
x = number of degrees the air would be cooled by the melting of the ice.

$$\text{Then } \frac{W\,(l+t-t)}{swv} = x = 4\tfrac{3}{4}°.$$

As, however, the air thrown in by the blower was mixed up with that which flowed into the hall through the open doors, the temperature of the hall was only reduced about one degree by the melting ice.

Taking the maximum temperature at 95°, and the maximum moisture in the air at nine grains per cubic foot; to reduce the temperature to 75°, and the relative humidity to 65, we must abstract three grains of water from each cubic foot, or $\frac{80{,}000 \times 3}{7{,}000}$ = 34.3 pounds from the whole quantity per minute. At the moment of the condensation of this water, from a vapor into a liquid, its latent heat is given out into the air; so that removing the vapor is a warming process. The additional extent which the air must be cooled to compensate for this is expressed by the formula—

$$x = \frac{W\,l}{s\,v\,w}$$

Where W = the weight of water in lbs. = 34.3
l = latent heat of the vapor.. = 1091°
s = specific heat of air....... = .2669
v = volume of air in cubic ft., = 80,000
w = weight of air per cubic ft., = .075
x = the number of degrees the air will be warmed by the condensation of the vapor.

With the above values, $x = 24°$.

The entire cooling effect must, therefore, be equivalent to 44°. This would require 24,000 pounds of ice to be melted per hour, or, say, 60 tons per daily session of five hours.

Coal is cheaper than ice per ton, and more conveniently stored and handled. One-sixth of the above quantity burned in the furnace of a steam-boiler will produce, through the medium of appropriate mechanism, an equal cooling effect upon the air. Machines are operated by the steam engine for the manufacture of ice, which produce cold by pumping off the vapor of sulphuric ether, or of the bisulphide of carbon; these liquids vaporizing rapidly at low temperatures if the pressure of the superincumbent atmosphere be removed; but the employment of such substances would be inadmissible in cooling the air for ventilation, as a slight leak in even one of the many necessary tubes would impair the purity of the air to a sensible and objectionable extent.

Mr. Stimers, therefore, proposes to employ the steam power to drive air-pumps to compress a portion of the air, making it hot, and while under this pressure to cool it down to the ordinary temperature by passing it through tubes surrounded by flowing water, (employing an apparatus precisely like the surface condenser of a steam engine,) and then let it expand into the duct. This expansion would be a cooling process exactly corresponding in extent to the heating one the air underwent when it was compressed, and by mixing this excessively cold air with the warm air from the blowers, the whole would be brought to the desired temperature.

It is mechanically convenient, in a machine of this kind, to compress two volumes of air into one, in the pumps. To learn how much such an amount of compression would elevate the temperature, a formula is given by Peclét*, as follows :

* *Traité de La Chaleur ; tome III, p.* 10.

Let θ = temperature before compression (Centigrade).
d = density before compression.
θ' = temperature after compression.
d' = density after compression.

$$\text{Then } \theta' = (274 + \theta)\left(\frac{d'}{d}\right)^{0.42} - 274.$$

In this case

$$\theta = 35° \ (= 95° \text{ Fahr.})$$
$$d = 1$$
$$d' = 2$$

and consequently

$$\theta' = 139.44° \text{ Cent. or } 283° \text{ Fahr.}$$

and the elevation of the temperature would be 188° Fahr.

To find how cold the air will be after its expansion, we have

$$\theta = \frac{\theta' + 274}{\left(\frac{d'}{d}\right)^{0.42}} - 274.$$

Assuming 20 lbs. pressure in the air condenser, and 75° Fahr. (23.89° C.) temperature of the water: as the heat was abstracted from the air it would be further condensed $\frac{1}{480}$ part with the departure of each additional degree, the pressure being maintained; hence we would have

$$\theta' = 23.89$$
$$d = 1.$$
$$d' = \frac{14.7 + 20}{14.7} = 2.36,$$

whence $\theta = -66.12°$ Cent. or $-87°$ Fahr.

This would be a reduction from its original temperature of 182°. This being slightly more than four times the amount of cooling force it is necessary to apply to the whole quantity of air furnished, one-fourth of that amount, or 20,000 cubic feet, will require to be passed through the pumps. The dimensions of the air-pumps and engines will be as follows:

Number of pumps	2
Diameter of pistons	65 inches.
Stroke of pistons	6 feet.
Double strokes per minute	40
Diameter of steam cylinders	45 inches.
Steam pressure	40 lbs.
Gross effective steam pressure	29 lbs.
Horse-power	1,200.

If the cold air was simply conveyed to the air-duct and mixed with the warm air from the blowers, it would be cooled down below the desired temperature, and a portion of the moisture it is desirable to abstract would be condensed in the form of a fog and carried along with the air into the hall, which would thus be filled with a cold, damp air, highly objectionable. It is necessary, therefore, to have the cold air introduced in a peculiar manner, such that not only may the moisture be abstracted, but that the exact amount removed may be subject of convenient and easy regulation by the engineer in the engine-room. The character of this regulation must necessarily be that the power exerted by the engine shall determine the extent of the cooling force, and that the amount of this which shall be devoted to reducing the temperature of the air, and that which is devoted to abstracting the moisture, shall be subject to a regulating lever, or hand-wheel; so that if the engineer moves this in one direction, the air will be made cooler and more moist, and if in the other, it is made warmer and dryer, the cooling engine continuing to run at the same rate.

To accomplish this it is proposed to erect, in each of the two cooling and drying chambers of the air ducts, a congeries of tubes somewhat similar to those employed for warming the air in cold weather, only there would be an additional chamber, or chest, at mid-height; in fact, two systems of tubes, one above the other; in other words, it would be two stories high. In the two upper chambers there would be openings in the bottom in all the spaces between the rows of tubes; these openings controlled by valves, and the valves appropriately connected with hand-levers in the engine room; there being one for a system of valves which would control the openings in every third space between the rows, and one for those in the remaining spaces. The aggregate area of the openings in the lesser system should equal the area of the pipe which brings the compressed air from the cooling engine; those in the other spaces, being of the same dimensions, would have in the aggregate twice this area. Then the compressed air should be conveyed by a pipe from the cooling engine to the lowest chamber, thence it would flow upward through the tubes into the upper chambers, then downward through the openings into the spaces between the tubes. The operation of this arrangement would be as follows:

Let us imagine a condition of the external air such as has been assumed for a maximum performance of the cooling engine. In this case let the openings in two-thirds the spaces between the tubes be closed, and those in the remaining spaces be wide open; the area of the whole being such that it would require a pressure of 20 pounds per square inch to drive all the air supplied by the pumps through them. It will be perceived that the pressure throughout, from the pumps to the exit, will be 20 pounds per square inch, and that, therefore, the temperature will be maintained at 75° while the air passes through the tubes. As the compressed air pours down between the two rows of tubes, and expands to the ordinary atmospheric pressure, its temperature will fall so suddenly that the moisture within it will be condensed, and part of it frozen into minute hail. The main portion of the air from the blowers will pass through the remaining spaces between the tubes, and as they are only one-eighth of an inch apart in the rows, they form, in effect, walls of separation between the warm and the cold air A sufficient quantity of the air from the blowers will, however, pass into the cooled spaces to carry forward the hail storm raging there, and as the hail and condensed moisture are carried along the narrow spaces they will come in contact with the surfaces of the tubes and be deposited upon them. The temperature of these will be too low to vaporize the moisture, but warm enough to melt the hail, and the water will run down them, as it does along the sides of an ice-water pitcher, to the bottom tube-sheet, whence it will pass off in proper drains prepared for it.

If the warm air issued from the dryer with the same velocity as the cold, exactly one-third of the whole amount would be excessively cooled, and nearly all its moisture extracted; but the great velocity with which the compressed air will pour into the spaces between the tubes, having only to be changed in its direction by the horizontal current from the blowers, will flow out with considerably greater velocity than the warm air from the remaining spaces; so that something more than one-third of the moisture contained in the whole amount of air will be deposited upon the tubes and carried away. In the case under consideration, exactly one-third is the amount it is desired to extract. The necessary reduction will be made by slightly opening the valves in the remaining spaces; the immediate effect of which will be to cool down all the tubes by causing a partial expansion of the air within them; so that the warm air will be cooled somewhat by coming in contact with the tubes, in addition to having some of the cold air mixed with it. This will lessen the extent to which the temperature will be reduced in the cold spaces, and, consequently, the amount of moisture will be condensed and extracted.

To enable the engineer in charge to control the condition of the air delivered to the hall, it is proposed to place pipes about three inches in diameter, and properly incased with a non-conductor, from the inlet duct, from the tempering ducts just beyond the moisteners, and from the hall; leading them through a convenient place in the engine room, for observation, to the suction openings in the blowers, which would cause a rapid flow of air through them, having the exact condition existing at the other ends of the pipes. Into each of these pipes, as they pass through the engine room, the wet and dry bulbs of a hygroscope would be inserted, which should plainly indicate the temperature and degree of moisture in the air passing through the pipes.

The method here recommended for drying the air when it is too moist, or when it is made so by reducing its temperature, is simply the adoption upon a small but sufficient scale of that employed by nature in effecting similar changes of weather.

Cost.—The actual cost of the complete apparatus described, is estimated by Mr. Stimers at $688,653. The following are some of the items:

Eight blowers and shafting for 200,000 c. ft. per min. each	$11,194
Pair of engines 750 H. P., with wood gear fly-wheel, erected complete	46,102
Four boilers, with 13,744 sq. ft. surface, and of 1,370 H. P.	63,416
Heating apparatus, with 44,582 sq. ft. block tin tube surface, with steam and water pipes and valves	123,018
Pair of condensing engines of 1,320 H. P., with 45 in. steam cylinders, and 65 in. air cylinders, 6 ft. stroke and a cooler with 9,000 sq. ft. brass tube surface, erected complete	94,552
Drying apparatus, with 5,570 sq. ft. block tin tube surface, with valves, complete,	30,754

Steam Farming Power.—It is but a very few years since a portable engine for farm use was a curiosity, nor is it so very long since such a thing was unheard of. Now, we find a single establishment capable of turning out a thousand yearly, of a design and finish equal to the best locomotive practice. There are at least four makers in Lincoln alone, one of them having magnificent works. More than 15,000 portable engines are known to have been sent out during the last eighteen years.—*Engineering.*

Fastening Cast Steel Driving Tyres. — The following rules, for shrinking on cast steel tyres, were issued by W. A. Robinson, Mechanical Superintendent of the Great Western (Canada) Railway:

1st. Both tyre and wheel must be perfectly cylindrical.

2d. These tyres are to have allowed, in their cold state, the amount of shrinkage shown in the following table, according to their respective diameters:

Letter of tyre.	Internal diameter of tyres.	ALLOWANCE FOR SHRINKAGE.		
		Decimal parts of an inch.	Fractional parts of an inch.	Wire gauge.
A	Ft. In.			
B	2 2¼	.014583	1–69	28
C	2 8	.017	1–56	27
D	2 9	.0183	1–54	26
E	3 2	.021	1–49	25
F	3 4½	.0225	1–44	24
G	3 8	.024	1–41	23
H	4 3¼	.028472	1–35	22
J	4 7	.0305	1–33	21
K	4 8	.031	1–32	21
L	5 2¼	.034583	1–29	20
M	5 3	.035	2–57	20
N	5 7⅞	.0377083	2–53	20
O	5 9	.0383	1–26	19

3d. Wood only is to be used to heat the tyres, and temperature must not be allowed to exceed a dark red glow in the shade, and all parts must be heated equally to insure uniform hardness and roundness. To facilitate the operation, each foreman is provided with a set of steel gauges corresponding to the above figures.—*American Railway Times.*

Steel Rails, Tyres and Fire Boxes. —The last report of Mr. Sayre, Superintendent and Engineer of the Lehigh Valley Railroad, treats these subjects as follows: "I have seen no reason to change my opinion of the value of steel rails as compared with iron; another year's wear has made no perceptible impression upon the 200 tons, the first of which was laid in May, 1864, none of which have broken or given out since last report. These rails have had a severe test, being in those places in the track where they are subject to the greatest wear, and being laid with a chair which is much inferior to the most approved joint now in use. * * * There is no longer any possible doubt as to the superiority of steel over iron in economy, as in every other respect." The report goes on to say that a large additional quantity of steel rails and a few steel headed rails have been contracted for.

As to steel tyres, the report say: "The experience of the past year has confirmed our favorable opinion of steel tyres. There were on the road at date of last report 57 locomotives furnished with steel tyres." This number has now been increased by 19 engines. "Although in one or two instances they have not done as well as we could wish, yet none of those of reliable manufacturers have failed, and the result in general has been very satisfactory. "The steel tyres of engine No. 25 put on December, 1863, have made 106,185 miles and are good still.

There were steel fire boxes on 14 engines at the date of former report. "All have given good satisfaction during the year except those of engines 50 and 51, which were not of good quality and have given us continual trouble. We now have in use 29 fire boxes of steel. The first one, put in January, 1862, is still good. All the engines contracted for, or which we build ourselves, are furnished with steel fire boxes and tyres."

The Darien Ship Canal.—By Mr. Cushing's mission, all political obstacles to the construction of this great work are removed; it is understood that American engineers have secured from the Government of New Granada, both the right of survey and the right of way across the Isthmus. A company including Peter Cooper, Marshall O. Roberts, Wm. H. Vanderbilt and other equally well known capitalists, was chartered by the New York Legislature last winter, and have since become fully organized as a joint stock company to undertake the work.

Many routes have been surveyed, but that from the Gulf of San Miguel to Caledonia Bay, and the one from Bayone River to the Gulf of San Blas have appeared most feasible. The latter route has deep and spacious harbors and would require but 30 miles of canal. The tunnel through the Cordilleras would be seven miles long, 100 ft. wide and 115 ft. high to allow steamers to pass, and even a first-class man-of-war, with her topmast and top-gallantmast struck and her yards braced.

THE HOOSAC TUNNEL.

The contract for this work, between the Messrs. Shanly and the State, made Dec. 24, 1868, is published in full in the "American Railway Times" of Jan. 30, 1869. The tunnel, central shaft and one track are to be completed by March 1, 1874; the price to be paid is $4,594,268. A delay in the rate of progress through the most difficult part is provided for, but the final delay must not exceed six months, and if the State decides that the contractors are not making the necessary average progress, it may give them three months' notice to quit the work. No payment is to be made to the contractors until they have earned $500,000; but 20 per cent. of the monthly amounts of pay earned is to be reserved for final payment on completion of the whole work; and, for 80 per cent. of each monthly amount, certificates in the sum of $200,000 each, bearing five per cent interest are to be issued, and to be paid in the order of their issue as often as it shall appear that the contractors have earned so much that after reserving the 20 per cent., the State will still retain in all, $500,000. The intention is that the State shall make no payment which will at any time reduce its security from the reserved fund of 20 per cent. below the said half million dollars.

The size of the tunnel, in rock, is 24 feet clear width and 20 feet height; where arching is required, 26 feet wide and $21\frac{1}{2}$ feet high. The central drain is 2 feet square. At the east end, the work done is 2,500 feet of tunnel, part of which is full size, and 2,782 feet of heading; the work to be done is tunnel enlargement 4,500 yards, heading enlargement 28,000 yards, tunnel extension 5,300 feet long=85,100 yards, trench and pipes 5,600 feet long, and the railroad track. At the central section the work done is sinking 583 feet of elliptical shaft 27 by 15 feet; the work to be done is to make a fire-proof floor with self-closing iron hatches, to sink the shaft to a depth of 1,030 feet (floor of tunnel) to set up two ten-inch iron pipes for power and ventilation, and to excavate the tunnel east and west to meet the end workings, with drain and track. The work done at the west end is a shaft 318 feet deep, 8 by 14 feet, and headings from it 1,609 feet east and westward to the west end, a pumping shaft 277 feet deep, and an auxiliary shaft 215 feet deep. The work to be done is enlarging the headings (52,800 yards), extending the tunnel east to meet central working, arching part of the tunnel with brick ($4\frac{1}{2}$ million bricks to be used), and the end with stone, having a suitable facade, and laying drain and track as above. The State gives the contractors the use of all plant, tools, &c., on hand.

As a more rapid progress of the work is required than drilling by hand labor would accomplish, upon each of the advance headings, between the east portal and west shaft, the contractors will be required to use pneumatic drills, working continuously not less then eight drills to a heading of eight feet height, with not less than 50 lb. air pressure, but with the liberty to employ the form of machine now in use in the tunnel, or any other drill of equal efficiency which they may prefer and provide at their own expense.

The prices for the work, fixed to determine the monthly amounts earned, are as follows:

Tunnel enlargement, per yard............	$16 00
Heading enlargement east end, per yard..	9 00
Heading enlargement west end, per yard..	9 75
Full size tunnel extension east end, pr yard	11 00
Full size tunnel extension central section, per yard............................	14 00
Full size tunnel extension west end, pr yard	12 00
Central drain with air and water pipes complete, per lineal foot	13 00
Sinking shaft (27×15 ft), per foot in depth	395 00
Pipes (10 in.) set in shaft depth..........	6 00
Arching with brick (at $9 per M.) per M..	22 00
Excavating and constructing 50 linear ft. of stone arch and filling.............	23,000 00

The extreme length of the tunnel will be about $4\frac{3}{4}$ miles, of which some three miles are yet to be excavated.

THE PITCH LAKE OF TRINIDAD ever and anon claims the attention of the public. At one time it is introduced as the source from which all the varieties of mineral oil, paraffine and asphaltum can be obtained. At another period it is to be employed to give greater illuminating power to our coal-gas, and some experiments of the Hon. Captain Cochrane, made at Woolwich, were highly favorable. Now we have the pitch of Trindad coming before us as an ingredient in artificial fuel for steamers. The bitumen is mixed with a certain quantity of charcoal: it is ground, and then made into bricks. Experiments made on board H.M.S. "Gannet," appeared to show that it possessed many valuable properties, but the amount of ash, arising from the earthy matter mixed with the petroleum, was somewhat objectionable. This can, however, in all probability, be obviated by greater attention in the process of manufacture.—*Quarterly Journal of Science.*

MINING.

PRESERVATION OF HEALTH AND LIFE—MINING MACHINERY.

From the "Quarterly Journal of Science."

The shortness of the average duration of a miner's life has often been the subject of the most serious consideration. The Royal Commission, of which Lord Kinnaird was the chairman, made this portion of their inquiry a most searching one. It is clear, from the evidence given by medical men and others, that the metalliferous miner suffers in health from climbing on the perpendicular ladders from great depths, from working in air deficient in oxygen, and from the severe labor of boring holes for blasting in confined levels. The constrained position of the man in "beating the borer," and the muscular effort necessary to deliver the heavy blow, act injuriously upon the heart and lungs.

The miner has been relieved to some extent from the effects of climbing, by the introduction of the "man-engine" (a movable rod with platforms fixed upon it, by which the miner is gradually lifted—without fatigue to himself—from any depth to the surface). The ventilation of the mines generally has been improved, but it is only within the present year that any actual experiment has been made in the mines on the use of machines for boring holes, worked by compressed air or steam. We have been favored, upon application, with the following report. We are glad to place this on record, as the commencement of an application of machinery to a most important purpose. We have no doubt that in a short time boring-machines will be generally adopted in our metal mines.

"Dœring's rock-boring engine has been worked on the 185 fathom level in Tincroft Mine, conjointly with another, from the 6th of January up to the present time, and has driven sixteen fathoms in hard Tin Capel, which Captain Teague considers would cost 20*l*. per fathom if driven by hand-labor. During the greater part of this time, in consequence of the air-pumps getting constantly out of repair, the machine was only worked by one (shift) corps of two men; and continuous working with three corps, comprising five men and one boy, only commenced on the 6th of July. Since this date nearly nine fathoms of ground have been driven, at a cost of 17*l*. 16*s*. 2*d*. per fathom. The following is the cost of working the machine during the last month:

	£.	s.	d.
Five miners and one boy	24	0	0
One boy to remove rubbish	2	0	0
Two enginemen at surface	6	0	0
One smith and boy	5	5	0
Oil, waste, and candles	3	9	0
Gun-cotton for blasting	4	10	0
Fuse	0	7	6
Sundries	0	3	0
Coals	6	0	0
Repairs	2	0	0
	£53	14	6

"In the above estimate the sum of 21*l*. 5*s*. is for expenses at the surface, which would be but slightly increased if three ends were driven instead of one—say about 2*l*. 15*s*. This would reduce the average cost per fathom 13*l*. 9*s*. 10*d*., instead of 17*l*. 18*s*. 2*d*. During these last three months one corps has been worked by one man and a boy, and the result has shown that they will drive as much ground with the machine as two men could do in the same time. (Signed) F. B. Dœring."

We find, during a recent visit to the Cornish mines, that the patentee is offering to contract for sinking shafts and driving levels upon such terms as will, without doubt, induce many mine adventurers at once to close engagements with him.

General Haupt's machine for boring is about to be introduced into the lead mines of Swaledale, in Yorkshire; and Mr. Lowe's machine is in use in several large railway cuttings and tunnels.

Our miners must (in consequence of improved mining abroad) direct their attention towards the application of machinery, so as to economize in every direction—not merely in the subterranean mining, but in all the surface operations. Necessity—the mother of invention—has already done much in this way; but there is yet ample room for very considerable improvement in the modes of working our mines, and in the methods of dressing the ores for the market.

In connection with this subject we may name—as we do with satisfaction—the increased desire on the part of the Cornish miners to avail themselves of the many advantages offered to them by the Science Classes of the "Miners' Association of Cornwall and Devonshire." We learn that four classes are now in operation in the mining districts around Helston, in which sixty working miners are proving themselves apt students of Chemistry, Mineralogy, Geology and Mechanics. One class of nearly thirty is no less actively engaged at Redruth, another in the mining parish of Gwennap, while a seventh have been recently been formed in the northern portion of the important mineral district of St. Just. The advantages which must result from these classes will, ere long, be felt in the improvement of mining and in the elevation of the miners.

The explosions of fire-damp in some of the coal mines of France has naturally drawn attention to the subject of ventilation. M. Galy-Cazalat, who has brought the matter before the Académie des Sciences, proposes the construction of vertical air-pits, the purpose of which would be to draw off the carburetted hydrogen as rapidly as it is formed, and thus prevent its mixing with the air of the mine. These "*cheminées d'aspiration*," as he calls them, will scarcely require very special description, the whole plan really resolving itself into a greatly increased number of shafts, by which the air in every part of the mine may be rapidly changed. There can be little doubt that great advantages would arise from such a system: but in the large and deep collieries of this country there are many serious difficulties standing in the way of its introduction.

M. Delaurier has brought before the Academy of Sciences a plan for *destroying* fire-damp in coal-mines. He proposes to place copper conductors of considerable thickness in the galleries; these are to be broken at intervals, and united by means of very thin gold wire, which is to be covered with sulphur. By passing a strong current of electricity through those conductors, the sulphur is ignited, and if any fire-damp be present it will be fired. This idea is by no means new. The Academy is said to have spoken approvingly of the proposed plan; but all coincided in the opinion that regular and powerful means of ventilation could in no case be dispensed with. The combustion of the *fire-damp* would produce *choke-damp*, which it would be necessary to remove. This plan, like many others which are from time to time brought forward, evidently originated with one who was but imperfectly acquainted with the conditions under which fire-damp is formed in a colliery.

CALCULATING AREAS.—Mr. J. L. Haddon, Chief Engineer to The Syrian Government, communicates to "the Engineer," his method of simplifying the tiresome calculations necessary for taking out areas, more especially when of curved or irregular surfaces

Principle.—Take paper of good manufacture (tracing or otherwise), and it will be found that its substance is very accurately distributed; any one square inch weighing precisely the same as any other—even in common papers it varies but slightly. The thicker the paper for my purpose the better.

Example.—Required to find the area of any map.

The paper on which the map is drawn is first to be accurately squared, the area thereof computed in inches, and its weight accurately ascertained. Next proceed to cut out carefully all that portion, the area of which is required, and weigh that also. Then as the weight of the whole is to weight of the portion cut out, so are their respective areas.

Suppose the scale of map to 20 miles = 1in., size of map, 20in. × 10in. = 200 square inches; weight of map, say, 2,000 grains. Then if weight of piece cut out is 1,500 grains, the area of it will be 150 square inches or 3,000 square miles.

In cases where the plan or map is valuable and it is not advisable to destroy it, a tracing of the part required has to be made, and the same process gone through for finding its area.

For iron sections, earthwork calculations, agricultural surveys, etc., it will be found most useful.

THE SICILIAN SULPHUR MINES have been long known. More than 600 mines have been at work, and at least 200 worked out and abandoned. The mining is of the most primitive character, the use of machinery being extremely limited. Not less than 22,000 people are occupied in working those mines, and the result is the production of sulphur to the value of not less than 17,600,000 francs per annum. The sulphur ores of Spain are now largely imported into England, and during the past year, not less than 500 tons of copper have been separated from sulphur-ash, after the sulphur has been expelled by burning, although the pyrites does not contain more than from 1 to 2 per cent. of that metal.

AGRICULTURAL IMPLEMENT MUSEUM.—Under the title of a Permanent Exhibition of Inventions and Improvements, a new section has been added to the Museum of Agriculture in Russia, the object which is to supply those who have invented or improved agricultural machines, implements or methods, with ready means of communication with agriculturists and the public. The machines, models, plans or drawings are to be exhibited gratis for six months, at the expiration of which time they will be returned to the inventors or destroyed, unless they should have been purchased for the Museum.

THE PIG IRON MANUFACTURE.

The great primary want of the manufacturer of malleable iron and steel, is better qualities of pig iron, such as can be produced from blast furnaces of the most approved construction. As a rule it may be set down that all the inferior ore and fuels may be worked to produce comparatively good results, when proper attention is paid to the details of construction of the furnaces, and preparing the materials for use, combined with skillful attention to the details of the manufacture. Every one familiar with this branch of science, is aware that the impurities contained in the materials are to some extent absorbed in the metal in the smelting operation, and that in numerous instances the fuel is very impure and imparts its deleterious properties to the pig metal. Hence it must be obvious that any means that will promote economy in the use of fuel will obviate this difficulty to the extent of the saving of the fuel. The improvement of pig iron is to be obtained by increased size and height of the furnace and by the use of a highly heated, uniform temperature of blast. A combination of these improvements are necessary to obtain the best results, for it has been found that with the same temperature of blast, in furnaces of fifteen feet bosh, given materials will produce inferior qualities of metal, while by using larger furnaces they produce improved grades of iron at a greatly diminished cost of production. To illustrate this we give the working of blast furnaces in the Cleveland district in England, using lean ores containing large percentages of sulphur and phosphorus, and as a rule with very inferior fuel. About six years ago the size of furnaces in this district varied from 14 feet to 18 feet boshes and about 50 feet high; the iron was unfit for any purpose where good quality was desired. Since the high, large furnaces have been adopted, with blast heated to 1,000° to 1,200°, the quality has improved to such an extent that the pig is now used for almost every purpose except the manufacture of steel. The most noted and successful examples of the large improved furnaces, are those of the Norton Iron Co. at Norton, England, and the Ferry Hill furnaces; they are respectively 25 feet boshes and 85 feet high, and 27 feet boshes and 102 feet high. These furnaces make the ton of best foundry iron with 17 to 19 cwts. of coke. The Norton furnaces, owing to more skillful engineering in the design and construction, produce more iron per week than the Ferry Hill furnaces, although considerably smaller. A large portion of the excellent results of these furnaces is attributed to the use of superior heating stoves for heating the blast, known as Player's patent. There are large numbers of these excellent stoves at each of the above works. The blast is generally heated to about 1,200°, which is maintained with great regularity. The Norton furnaces were designed and built by John Player, an engineer of considerable experience, now residing in New York. The production of one of these furnaces is nearly 600 tons per week. The ores average 42 per cent.

The commercial value of the improved furnaces, as compared with the old style now obselete in Cleveland, is so great that upwards of 50 furnaces in good repair, are abandoned and will never be blown in again. Six years ago many furnaces "blew out," when pig iron reached 65s. per ton with labor and material cheaper than they now are; since then the large furnaces have been put at work and can sell pig iron at a profit at 40s. per ton. At many works in the United States, by remodeling and adding the Player stoves, results are now obtained that approximate nearly to those given in the large English furnaces; this is to be attributed to the superiority of the ores and fuel used here, more especially our admirable anthracite, than which there is no better fuel for the manufacture of pig iron, excepting of course charcoal, which is gradually becoming scarcer every year and is left out generally in calculations for a large continued business. There are also many instances among our American furnaces (to which we shall refer in detail on another occasion) of larger production and improved quality, due to the improved hot blast stove; the reduction of fuel in some instances is said to be 50 per cent with a corresponding increase in the production of the furnace and with the highest grade of iron where only ordinary iron was previously made.

The advantages of large furnaces (when suited to the materials) over smaller ones is so great that pig iron makers should no longer hazard the building of small furnaces; the difference in the cost of production in two years will clear the cost of the large furnace. From the results abroad, and the better practice just beginning here, it will be seen that improvements actually exist, which, when fully applied to this industry in America, will revolutionize, not only the manufacture of pig iron, but the manufacture of cheap and good malleable iron and steel.

FLYING MACHINES.

PRINCIPLES—EXPERIMENTS—THE LIGHTEST STEAM ENGINE.

Condensed from a paper in the "Popular Science Review," by Fred. W. Brearey, Honorary Secretary to the Aëronautical Society of Great Britain.

In its normal state, the air is inapplicable as a power, but it is capable of becoming an overwhelming power, either by natural or artificial causes, as in the whirlwind and tornado or by rushing forcibly through it, as would be exemplified were the sails of a windmill rotated rapidly against it. Thus the bird may create for itself in a calm, by the agitation of its wing-surface, the power which supports and prolongs its flight in a horizontal or ascending line ; but is also capable, in the calm of a sultry summer's day, by the mere momentum of its own weight, of gliding for an immense distance upon an unyielding plane, thus converting the inert air into a fulcrum or support. In such a case, two only of the three requisites for successful flight are brought into action, viz, surface and weight, the third, force, being held in reserve for extraordinary occasions.

There can be no question in dispute, as to the possibility of so manipulating and inclining the surface of a descending body, as to prolong the gliding motion, and convert it into one obedient in some degree to the will of the operator. When the two antagonistic forces, gravity and atmospheric resistance, are brought into operation, the result is a course, arrested and diverted in some direction, either by what we call accident, or design. Hitherto, as in the case of the parachute, accidental circumstances have alone determined the deviation. It has been the great desire of man for ages to supply, either in his own person, or by the aid of apparatus, or by self-acting machinery, the third requirement for flight, viz, force, which may enable him to impel a plane surface at the proper angle of inclination against the air, and thus to nullify the effect of gravity.

Necessarily, the relative proportion of sustaining surface to weight, and of power to uphold and propel that weight, have occupied much attention. Considerable misconception has existed upon these two points, and to this is mainly due the tardy progress of the science of aëronautics. In England, the subject has really never engaged the attention of scientific men, except under the form of aërostation, in the earlier years of its discovery. There have ever been persistent believers and experimenters, and in the influential association which has been organized under the name of the Aëronautical Society of Great Britain, embracing amongst its supporters some of the first scentific men of the day, with the Duke of Argyll as President, the subject of aëronautics has been elevated into a science.

In a paper by M. De Lucy of Paris, there is detailed the result of actual experiments made by the author, with a view of determining the extent of wing surface to the weight to be sustained, and of the force requisite to raise and impel in horizontal flight. The author asserts, that there is an unchangeable law, to which he has never found any exception, amongst the considerable number of birds and insects, whose weight and measurements he has taken, viz, that the smaller and lighter the winged animal is, the greater is the comparative surface. Thus in comparing insects with one another ; the gnat, which weighs 460 times less than the stag-beetle has 14 times greater relative surface. The lady-bird which weighs 150 times less than the stag-beetle, possesses 5 times more relative surface, etc. It is the same with birds. The sparrow which weighs about ten times less than the pigeon, has twice as much relative surface. The pigeon which weighs about eight times less than the stork, has twice as much relative surface. The sparrow which weighs 339 less than the Australian crane, possessess seven times more relative surface, etc. If we now compare the insects and the birds, the gradation will become even much more striking. The gnat, for example, which weighs 97,000 times less than the pigeon, has 40 times more relative surface ; it weighs 3,000,000 times less than the crane of Australia, and possesses relatively 140 times more surface than this latter, which is the heaviest bird the author had weighed, and it was that which had the smallest amount of surface, the weight being 20 lbs. 15 oz. $2\frac{1}{4}$ dr. avoirdupois, and the surface (referred to the kilogramme 2 lbs. 3.27 oz.) 139 square inches ; yet of all traveling birds, they undertake the longest and most remote journeys, and, with the exception of the eagle, elevate themselves highest, and maintain flight the longest.

M. de Lucy remarks, that if the law of surface in inverse ratio to weight be regarded, the cause of all the errors which have been committed will be readily understood; for a mathematician who should select as his type an excellent bird of flight such as the swallow, by ascertaining its weight and surface, will apportion nearly one meter or 1,550 sq. in. to the kilogramme, and consequently 75 meters for a man of 75 kilogrammes, that is to say, about 165 lbs. would require a surface of 116,250 sq. in. Should he select the pigeon, he will arrive at a result quite different, because the pigeon being heavier than the swallow has a surface relatively smaller. According to this type, he would arrive at the conclusion that only 20 meters of surface or 31,000 sq. in. would be requisite for a man of the same weight. The example of the crane of Australia, would give to a man a surface of no more than 10,850 sq. in. Again, should he select a type amongst insects, for example the blue dragon-fly whose flight is so rapid, he would discover the weight to be rather more than $\frac{1}{2}$ grain, and surface nearly $\frac{2}{5}$ of a square inch, which referred to the selected standard of comparison would give 9,416 sq. in. and for the man 705,800 sq. in. Were we to determine the amount of sustaining surface requisite for the man from some of the butterfly tribe, whose wings are so prodigiously expanded in comparison with their weight, we should arrive at results so much in excess of these dimensions, that the construction of the apparatus would be impossible.

The author next proceeds to state that "The law of surface, in inverse ratio to weight, would naturally tend to lead us to this conclusion—viz: that the heaviest-winged animal, having the least surface, ought in return to possess the greatest force." But he proceeds to disprove this assumption, by showing, that the muscular force of insects is much greater than that of birds, and he adduces various well-known instances. Upon the supposition that his facts, and the theory founded on them, are correct, it will be a fair hypothesis to assume that where large wing-surface is given to insects, the provision is accompanied by the relative power to control it, in compensation for absence of weight, which we have seen is during descent a power of itself, and is taken advantage of by some birds, in gliding, or soaring against a breeze. For such purposes, weight is a necessity, and therefore we never see any similar method of flight in the winged insect tribe.

The first recorded and scientifically based attempt to connect plane surface and weight, in relative proportion to one another, was that of which all the world was cognizant in 1842, patented by Henson—a plan resulting from conversation between Henson and Stringfellow. "The amount of canvas or oiled silk necessary for buoying up the machine, was stated to be equal to one square foot for each half pound weight, the whole apparatus weighing about 3,000 lbs., and the area of surface spread out to support it, 4,500 square feet in the two wings, and 1,500 in the tail, making altogether 6,000 square feet." But this machine was never constructed; for after two abortive attempts to manufacture models, which should represent the dimensions before-named, the two inventors commenced their experiments under a variety of forms. Mr. Stringfellow frequently availed himself of the express train, taking with him an arrangement for testing the resistance of different angles against the air, at high speed, and he states that those experiments only tended to prove, that any guess-work was better than the calculations hitherto made by writers on the subject. In 1844, they commenced the construction of a model which measured twenty feet from tip to tip of wing, by three and a half feet wide, giving seventy feet of sustaining surface in the wings, and about ten more in the tail. The weight was from twenty-five to twenty-eight pounds.

An inclined plane was constructed, down which the machine was to glide, and it was so arranged that the power should be maintained by a steam engine, working two four-bladed propellers, each three feet in diameter, at a rate of 300 revolutions per minute. For seven weeks the two experimenters continued their labors. In the language of Mr. Stringfellow: "The machine was saturated with wet from a deposit of dew, so that anything like a trial was impossible by night. I did not consider we could get the silk tight and rigid enough. Indeed, the framework altogether was too weak. The steam engine was the best part. Our want of success was not for want of power or sustaining surface, but for want of proper adaptation of the means to the end of the various parts." Many trials by day down inclined wide rails showed a faulty construction, and its lightness proved an obstacle to its successfully contending with the ground currents.

Shortly after this, Mr. Henson left for America, and Mr. Stringfellow, far from discouraged, renewed alone his experiments. In 1846 he commenced a smaller model for indoor trial, and, although very imperfect, it was the most successful of his attempts. The sustaining planes were much like the wings of a bird. They were ten feet from tip to tip, feathered at the back edge, and curved a little on the under side. The plane was two feet across at its widest part; sustaining surface, seventeen square feet; and the propellers were sixteen inches in diameter, with four blades occupying three-fourths of the area of circumference, set at an angle of sixty degrees. The cylinder of the steam engine was three-fourths of an inch in diameter; length of stroke, two inches; bevel gear on crank shaft, giving three revolutions of the propellers to one stroke of the engine. The weight of the entire model and engine was six pounds, and with water and fuel, it did not exceed six and a half pounds.

The room which he had available for experiments did not measure above twenty-two yards in length, and was rather contracted in height, so that he was obliged to keep his starting wires very low. He found, however, upon setting his engine in motion, that in one-third the length of its run upon the extended wire, the machine was enabled to sustain itself; and upon its reaching the point of self-detachment, it gradually rose, until it reached the further end of the room, where there was canvas fixed to receive it. It frequently, during these experiments, rose after leaving the wire, as much as one in seven. He afterwards experimented with greater success at the Cremorne Gardens. Having now *demonstrated the practicability of making a steam-engine fly*, and finding nothing but a pecuniary loss, and little honor, this experimenter rested for a long time, satisfied with what he had effected.

In a paper read by Mr. F. H. Wenham, at the Society of Arts, on the occasion of a meeting of the Aëronautical Society, there occurred the following observation: "Having remarked how thin a stratum of air is displaced beneath the wings of a bird in rapid flight, it follows, that in order to obtain the necessary *length* of plane for supporting heavy weights, the surfaces may be superposed, or placed in parallel rows, with an interval between them. A dozen pelicans may fly one above the other, without mutual impediment, as if framed together; and it is thus shown, how two hundredweight may be supported in a transverse distance of only ten feet." Mr. Stringfellow having been again called out by the Aëronautical Society, eagerly grasped this idea and set about constructing the model which he exhibited at the Crystal Palace in 1868. This model contained in its three planes, a sustaining surface of twenty-eight square feet, besides the tail. Its weight, with engine, boiler, fuel and water, was under twelve pounds. It possessed in its steam-engine one third of the power of a horse, and its weight was only that of a goose. It will be seen, therefore, that the sustaining surface was more than two feet to the pound, always supposing that the system of superposing the planes, was efficiently represented in so small a model, which may reasonably be doubted. This proportion of weight to surface is more than double that which is generally allowed to be necessary. The necessity, however, for providing even for as little as one pound for every square foot, would not exist if a certain speed could be maintained.

It has been observed by several reporters for the press that the model showed a decided tendency to an upward course during its hundred yards run at the Crystal Palace, but upon farther trial, when freed from its support it descended an incline with apparent lightness, until caught in the canvas, but the general impression conveyed was this—that had there been sufficient fall, it would have recovered itself, and proceeded onwards. Subsequently, Mr. Stringfellow lengthened the propellers, and added nine feet to the central plane, which, with other alterations, decidedly deteriorated its aërial capabilities. He is now engaged in experimenting with a view of ultimately constructing a large machine that would be sufficient to carry a person to guide and conduct it. On this scale he would avoid many difficulties which are inseparable from small models.

As Mr. Stringfellow gained the prize of £100 for "*the lighest steam-engine in proportion to its power*," and as the engine which propelled the model at the Crystal Palace differed from that but in dimensions, we append a description of the engine, which was given in the report upon Exhibition published by the Aëronautical Society: "The steam engine does not differ from an ordinary one, except in the precautions to ensure lightness. The two-inch cylinder is of very thin brass tube; the covers, flanges and glands are also as light as can be made, consistently with strength; the ports and passages are in one separate piece, screwed on; the piston-rod passes through each end of the cylinder, and by means of long connecting rods, works in opposite directions two cranks, fitted to the axes of two four-bladed screws, three feet in diameter; two light bars extend from the crank-shaft down each side of the cylinder: these sustain the thrust of the piston, and a framing is thus almost dispensed with. The boiler consists of a number of inverted cones, made of very thin sheet copper, with the joints soldered with silver solder. Each cone is closed with a hemispherical cap. The cones are placed in parallel rows; the bottom ends, or apexes, of the series are all connected together by water-tubes; and from the hemispherical tops a small steam pipe conveys the steam away to a cylindrical chamber above the system: this is set in the smoke-box, and serves as a super-heater, and the steam is quite dried therein. The cones are not liable to prime, as the water surface for the escape of the steam is extensive, and the steam rises clear from the generating surfaces. The fire space between the bases being large and free, this form of boiler is particularly well adapted for burning liquid fuels. The cylinder is two inches in diameter, stroke three inches, boiler pressure 100 lbs. per square inch. The engine makes 300 revolutions per minute. In three minutes after lighting the fuel, the pressure was 30 lbs.; in five minutes, 50 lbs.; and in seven minutes its full working pressure of 100 lbs., driving two four-bladed screw propellers, three feet in diameter, at 300 revolutions per minute.

In an article entitled "Swimming or Flying," contributed to the "Times," (April 9, 1868,) the author comments upon the possibility of man's sustaining himself by his own muscular exertion, and especially refers to Mr. Charles Spencer's assertion that he could not only effect this feat, but that he could sustain flight for several yards. Mr. Spencer constructed an apparatus, and by its means he avers that he has proved, that 110 square feet properly disposed, is sufficient to sustain 158 lbs. weight. With such an apparatus, composed of plane and wings, he states, that running down a small incline in the open air, and jumping from the ground, he has by the action of the wings, sustained flight to the extent of 120 feet. The framework of this apparatus, was a marvel of lightness and strength, composed of steel umbrella wires and wicker-work. Length of tail, 18 ft.; width at the end, 8 ft.; depth of keel at the end, 4 ft.; weight of tail, 15 lbs.; area of tail, 72 sq. ft. Length of wing, 7 ft.; width at the widest part, 4 feet; area, 15 sq. ft.; weight, $1\frac{1}{2}$ lb.; weight of the whole—tail 15 lbs.; wings, 3 lbs. = 18 lbs.; weight of himself, 10 stone, and sustaining surface, 110 sq. ft.; total weight of himself and apparatus, 158 lbs.; making not quite $1\frac{1}{2}$ lb. to the square foot. Owing to the wicker-work—which is made to fit tight round the body—causing pain, and otherwise obstructing his movements, he was unable to satisfy the curiosity of the public, and he is now reconstructing that portion, and substituting a stronger material for the covering. According to De Lucy's theory of surface in inverse ratio to weight, the sustaining surface, instead of being 110 square feet, need only have been about 31 square feet, always supposing that the surface was effectively disposed, which in Spencer's apparatus may be very properly questioned.

We come now to the description of another—Gibson's machine. Dissimilar to either of the former inventions, which respectively consisted of plane—and plane with wings—this was expected to obey the action of the wings alone. The mechanical action at the command of the operator was intended to be controlled by the downward pressure of each leg alternately, assisted by the arms. The machine therefore consisted of a framework, to which were attached four wings, so that by pressure upon one treadle, two flew up feathered, and two descended with an impact upon the air.

In a previously constructed apparatus provided with two wings only, Gibson states that a man weighing $10\frac{1}{2}$ stone repeatedly raised himself from the ground from 12 to 18 inches, but that he could not sustain himself, because the wings being so heavy, he was not able to repeat the stroke. Each wing was 12 feet long, $1\frac{1}{2}$ feet across at the wider part, and 1 foot at the narrower; surface of both wings 37 square feet; weight of each wing, 10 lbs.; frame and rods, 21 lbs.; weight of man, $10\frac{1}{2}$ stone; giving about 5 lbs. to each foot of sustaining surface, a condition which severely tests the theory of inverse proportion of surface to weight. The four-winged contrivance sent to the Crystal Palace was found to be too heavy for trial, but the inventor's enthusiasm seems to be quite equal to the construction of another and lighter apparatus for further exhibition. It must be remarked, as an interesting feature in Gibson's apparatus, that the total weight of the man and apparatus, as compared with the surface, gives on De Lucy's theory, about 38 square feet as the proper sustaining surface, or one foot more than it possesses—taking for our calculations, the Australian crane, and the theory of inverse proportion with its margin of from eight to ten times.

Experiments can alone determine the true path to success, and it is encouraging to find that these are now aiding in the determination of the question. It is possible that we may shortly witness some more advanced attempts, and should they prove to be failures in the practical solution of the problem, it will perhaps be remembered that previous failures having led to increased knowledge, so future success may result from their repetition.

IMPROVED GAS-HEATING FURNACE.

ESTIMATE OF THE QUANTITY OF FUEL REQUIRED FOR CAST STEEL, WITH THE SIEMENS FURNACE, AND BY THE NEW PROCESS OF PARTIAL ELIMINATION OF NITROGEN, OF M. CH. SCHINTZ, OF STRASBOURG.

Translated from "Le Génie Industriel."

We announced in our last number the appearance of a work of M. Schintz, on the High Furnace. Before giving an analysis of it, as we promised, we believe our readers will be interested in the following analysis upon a kindred subject, which M. Schintz has kindly communicated.

In the "Oestreichichen Zeitschrift für Bergüttenmanner," No. 26, 1868, M. Kupelwieser, Professor in the School of Mines of Leoben, showed that the expense of fuel in the production of steel, by the Martin process, does not greatly exceed that by the Bessemer. This is surprising, in view of the fact that the intense heat by the latter process is produced by the small percentage of carbon in the gray metal, while in the Martin process, as at present conducted, the operation lasts seven or eight hours, and consumes at least 1.5 kilogrammes of lignite for every kil. of steel produced. Although the consumption by the latter process is so great, the small ultimate difference between the two is due to the fact that for the Bessemer, gray iron is used, and for the Martin, white iron, and the production of the latter, in the high furnace, requires but one-half to one-third the quantity of coal necessary for the former.

I have found the computations of M. Kupelwieser quite accurate, though I by no means agree with him when he undertakes to show that the regenerating furnace of M. Siemens is preferable to all others for the Martin process; for it is easy to demonstrate the reverse. I have before me the plan of a reheating furnace, on the Siemens plan, which ought to consume pretty nearly as much fuel as a cast steel furnace; the only difference being that the latter is only about half as long. A charge for the steel furnace is composed of

.888 kil. white pig, .664 kil. puddle bar and crude steel,	} 1.552 kil. = .21555 c. meters of casting.
.47 kil. ore, . . .	pure and rich, which is decomposed into $F\ e\ O$ and $C\ O$—. Volume of the $C\ O$ 1.5 cubic meters.

Assuming that the melted metal is .15 m. thick, the surface will be $\frac{.21555}{.15} = 1.437$ sq. met., and allowing .5 m. for the breadth, the length will be $\frac{1.437}{.5} = 2.8$ met. But in the Siemens furnace we must add the bridges which hold the metal, the flues which conduct the gas, and the air and the flues at the other end which lead off the products of combustion. All this augments the length of the melting furnace, and gives us, instead of 2.8 m., a length of 4.2 m., and the exterior surface of the arch and side walls becomes 10 sq. m., while without these necessary accessories this surface would be but 3.42 sq m. Now, making all due allowance for what takes place in the regenerators themselves, their use is a source of great loss of heat, for we have just shown that the loss of heat by transmission is excessive, compared with the useful effect. The transmission for a unit of surface, per hour, is

$$t' = \frac{T - t''}{1 + Q\frac{e}{c}} + t''\,Q.$$

T being the temperature of the furnace; t'' that of the atmosphere

$$Q = \frac{S\ m\left(\frac{t}{a-1}\right) a\ l + L\ u\ t^{6}}{t}$$ (formula of Dulong).

$S = 3.62$, $L = 1.988 = 20°$, $e = .2$, $c = 0.8$ at least, $e =$ thickness of walls, $C =$ the conductibility of the materials of which the walls are composed.

M. Ed. Becquerel has found that the melting point of decarburized iron is between 1,350° and 1,400° Cent. There is no probability that the temperature of the furnace exceeds 1,400° C., otherwise the operation would not last seven or eight hours. Supposing, then, that $T = 1{,}400°$ and $t'' = 20°$, the theoretical transmission is $\frac{1{,}400 - 20}{1 + Q{:}\frac{2}{8}} + 20\ Q = 4{,}892$ calories ($Q = 17.92$). My own researches have shown that the actual transmission of heat is from three to thirteen times greater (according to the temperature) than the theoretical transmission, for the surrounding air being always in movement, and becoming warm, carries off great quantities of heat. The effective transmission in this case cannot fall short of 134,892 = 63,596 calories per sq. met. per hour. For 10.24 sq. m. this becomes 651,223 calories. But we must remember that the value of L in the formula of Dulong is less for a horizontal than for a vertical surface. We must, therefore, deduct one-third upon two-thirds of the calculated transmission, which amounts to 71,501. Deducting this 651,223 — 71,501 = 579,722 calories.

To melt one kil. of decarburized iron the heat consumed is $1{,}400 \times .16585$ (.16585 being the specific heat of iron at 1,400°) = 232 calories. Latent heat of fusion = 160 + (.16585 — .11379) 1,400 = 233 calories. Total heat consumed in melting one kil. of iron, 465 cal., and for 1,552 kil., the entire charge $465 \times 1{,}552 = 721{,}680$, and per hour, allowing eight hours for the operation, $\frac{721{,}680}{8} = 90{,}210$ cal., which, added to the transmission above calculated, gives for the number of calories employed in the furnace of fusion, 669,932.

The fuel employed at Leoben was lignite, of which the calorific power is 5,419 calories per kil. for a perfect combustion, and on the supposition that the gas arrives in the furnace at the temperature it gets in the generator. It is known that in the Siemens furnace it is necessary to cool the gas and condense the hydro-carbon vapors, because if they get into the regenerator they are decomposed there, and give off a deposit of carbon which obstructs the flues; but as the heat so lost is restored by the regenerator itself, we may consider the gas as being in the same condition as if it had not been cooled. Hence, the pyrometric equivalent of the lignite, for a furnace temperature of 1,400°, is $5{,}419 - 1{,}400 \times 2.15525 = 2{,}402$ calories, and the quantity carried off per kil. of lignite = 3,017 calories. Dividing the consumption of heat in the furnace by the pyrometric equivalent, we obtain $\frac{669{,}932}{2{,}402} = 279$ kil. of lignite necessary for this consumption. But the actual expense is 291 kil., and thus there remains an excess of 291 — 279 = 12 kil., showing that a portion of the gas is not burned in the furnace, but in the regenerator. The same thing may be seen taking place in the largest glass furnaces, which are six to eight meters long, and I have noticed that there is always some flame at the end of the fire circuit, which proves that the gas is burned gradually. The result is, that in the Siemens system the gas and air are not thoroughly enough in contact to make a perfect combustion. If, now, the length of fire circuit, for accomplishing approximately the same result, is only four meters, it need not surprise anybody if the combustion is completed in the regenerator. The following are the quantities of heat which the regenerator receives per hour:

279 kil. lig. at 3,017 = 841,733 } = 906,771
12 " " 5,419 = 65,028 } calories.

The capacity of the four chambers of the regenerator is 42,336 cubic met., of which $\frac{1}{3}$ is of solid fire-brick, = 14,112 cubic met. at 1.9 [specific gravity] = 26,812 kil., and the capacity for heat = $26{,}812 \times .24 = 6{,}435$ calories.

The maximum of heat in the regenerator, when the products of combustion cease to pass it, is

Entrance temp. $= \frac{906{,}771}{291 .\ 2.15525} = 1{,}446°$.

Exit temp., ... 300°.

Mean, ... 873°.

Maximum capacity $873 \times 6{,}435 = 5{,}617{,}755$ cal.

It is at the minimum, just after the air and gas have ceased to pass, and hence it is minus the heat introduced per hour, which is, as above, 906,771, making 5,617,755 — 906,771 = 4,710,984 calories, and the mean temperature of this regenerator is not above $\frac{4{,}710{,}984}{6{,}435} = 732°$.

The exterior surface of the regenerator

measures 46.02 sq. met., the thickness of the walls is $e = .3$, their conducting power at least $.6 = c$. Hence the mean temperature regulating the transmission is $\frac{873+732}{2} = 802°$, and the theoretic transmission becomes $\frac{802-20}{1+Q:\frac{3}{6}} + 20\ Q = 1{,}537$ cal.

The actual transmission is 7,753 calories, and the total

		Calories.
Transmission	$= 46.2 \times 7{,}753 =$	358,188
The loss by escape,	$300 \times 291 \times 2.15815 =$	188,100
Useful effect, ...		360,483
Total heat equal to that introduced, ...		906,771

The quantity of heat lost by the gas in cooling is 303,804 calories. Hence all the gain we get from the regenerator is 56,679 calories—just enough to raise the temperature of the air to 289°.

These calculations are the results of a system of long continued and very careful experiments, and are perfectly in harmony with the facts, for if the temperature of the furnace is higher than the melting point of the metal, the operation would be complete in much less time than seven to eight hours.

I have proved, by the formula of Cauchy, that supposing the metal to be penetrated with a volume of carbonic oxide equal to its own, while the bed of coal is $2 \times .15$ met., the conductibility will be such that in a few minutes the mass will take the temperature of the furnace. Now, to produce steel much more cheaply than by the Bessemer process (which leaves a great deal to be dedesired on the score of certainty of quality in the product), we should have to devise a method of heating which would admit of a higher temperature. It need not necessarily be very much higher—in fact an addition of 100° would probably be sufficient to reduce the length of the operation one half, and hence, even supposing the quantity of fuel burned per hour to be the same, there would still be an economy of one-half the fuel, of labor, interest on capital, etc. We shall proceed then to show that it is practicable to increase the heat of the furnace at a smaller expense of fuel.

This method consists essentially in the production of a gas which contains a smaller proportion of nitrogen than is usual in processes now employed.

To produce this gas we may decompose by heat carbonate of lime, and pass the carbonic acid given off over coal dust or some substance containing carbon. This will give us pure carbonic oxide. By burning this with the quantity of air necessary to reproduce the carbonic acid, and effecting this operation within a combustible solid, which will again reduce the $C\,O_2$ to $C\,O$, this last product will be mixed with only one-half the volume of nitrogen which ordinarily accompanies the gas produced by combustion. The pure oxide of carbon will have, on leaving the chamber in which it is produced, a temperature of 1,000°. For every kil. of carbon which it contains it will yield 2,400 calories, to which we must add $1{,}000 \times .2479 \times 2\ 333 = 578$ cal. If the air used in the combustion is introduced at 300°, it adds $300 \times .2377 \times 5.7515 = 410$ cal., which, added to the foregoing, is 3,388 cal. On the other hand, the reduction of the carbonic acid produced, absorbes 2,400 cal., and deducting this the quantity of heat contained by the gas will be 988 cal. This gas is composed of

4.6666 k. $C\,O$ whose spec. heat = 1.1568 }
3.4418 k. N whose spec. heat = .8392 } 1.9966

The temperature of the mixture will therefore be $\frac{988}{1.9966} = 495°$. The burning of 4.6666 k. of $C\,O$ in the furnace will yield

		Calories.
4.6666×2400, ...	=	11,200
The gas brings with it, . .	=	988
The air at 300° brings $11.5030 \times 300 \times .2377$, ...	=	820
Total, ...		13,008

The products are

7.3333 k. $C\,O_2$ spec. heat, 1,587 }
10.5458 k. spec. heat, 2,573 } 4,160

and the initial temperature is $\frac{13{,}008}{4{,}160} = C$ .3127° C.

For 1 kil. of lignite (allowing that $\frac{1}{3}$ kil. of carbon is absorbed by the carbonic acid given off by the carbonate of lime, which contains 0.20565 k.) there will be required

1.7136 k. carb. lime, . . . 20,563 cal.
3333 } 1.0000 lignite, . . { 20,563 "
6667 } { 41,126 "

and we have $.41126\ C = 95061\ C\ O$, which requires $.54855\ O + 1.8171\ N = 2.236545$ kil. of air, and becomes 1.50796 k. $C\,O_2$ +

1.8171 N. To reduce again this $C\,O_2$ to $C\,O$, will take .41126 C. contained in 0.6667 k. of lignite, —0.6667 k. lignite containing 0.41126 k. calories, 0.17994 elements of water, 0.01346 free hydrogen. So we shall have in the gas produced

kil.		kil.	
1.91992 $C\,O$,	which requires	1.0967 O	
.01346 H,	" "	.10768 O	= 3.9908 N
.17994 $H\,O$,	" "	1.20438 O	k.
1.8171 N,	" "	5.19018 air	=5.1918 air

The gas produced by C and $Ca\,O$, $C\,O_2$, receives in the chamber where it is produced the temperature of 1000°, and consequently brings 1000 × .95961 × .2479 = 238 cal.

The air to be burned with it, 300×2.36545×.2377, . .	= 168 "
Total,.	406 "

The production and absorption of heat by the reduction cancelling each other, need not be carried forward in the account, but there will be .17994 $H\,O$ to evaporate, which will take .17994 × 536.67 =96 calories to be deducted, leaving in the gas 310 cal.

The following is the composition and specific heat of the gas:

k.				
1.91922 $C\,O$	× .2479	= .4757		
.01346 H	× 3.4046	= .0458		
.17994 $H\,O$	× .475	= .0855		1.0504
1.8171 N	.244	= .4434		

Hence the temp. will be $\frac{310}{1.0504} = 295°$ C.

By burning this gas in the furnace we produce

k.	cal.	cal.	
1.91922 $C\,O$ at	2400	= 4,606	
.01346 H at	34000	= 457	5743 cal.
5.19518 hot air at	300	= 370	
Brought in by the gas		310	

The specific heat of the product is

k.			
3.01592 $C\,O_2$	0.2164 =	.65262	
.30108 $H\,O$	.475 =	.14301	2.21273
5.8079 N	244 =	1.41710	

The initial temperature $= \frac{5743}{2.21173} = 2596°$ C. The pyrometric equivalents for the following temperatures will be

For	1400°	1450°	1500	1550	
Pyr. Eq.	2645	2535	2424	2314	cal.
Heat passing off,	3098	3208	3319	3429	cal.

Hence it appears that the same weight and kind of fuel will produce a furnace temperature of 1500°, while without the elimination of nitrogen it would give but 1400°. It now remains to see whether the heat passing off from the furnace will be sufficient to decompose the carbonate of lime, and to reduce the carbonic acid formed to carbonic oxide.

For the same dimensions of the furnace proper the area of the arch and walls reduces to 3.42 sq. met., because we no longer need the entrance and exit flues, nor the bridges for holding the melted metal. If we suppose the times corresponding to temperatures to be as follows,

Hours,	8	$6\frac{1}{2}$	5	$4\frac{1}{2}$
Temp.,	1400	1450	1500	1550

we shall not have exaggerated the advantage, which gives us as useful effect, per hour,

$$\frac{721680}{8} = 90210$$

$$\frac{721680}{6.5} = 111028$$

$$\frac{721680}{5} = 144336$$

$$\frac{721680}{4.5} = 162573$$

Observing that this arch is one-half the whole surface, and using the same notation as before, we shall find the actual transmission, per square meter, per hour, to be

				Cal.
	47697	49187	51114	53109
and for 3.42 sq. m.....	163123	168219	174810	181633
Useful effect ..	90210	111028	144336	162573
Total heat ..	253358	279247	319146	344206

These figures, divided by their pyrometric equivalents, give for the expense of fuel per hour

96 110 132 149 kil. lignite,

and the quantities of heat passing off,

297408 352880 438108 510921 cal.

For 1 kil. lignite we must decompose 1.7136 kil. of carbonate of lime, which requires, in order to be heated to 1000°

1.7136 × .675083 × 1000 = .	1157 cal.
Heat of combination 1.7136×251	430 "
Heat of $C\,O_2$ first formed . . .	1587 "
Heat to reduce it to $C\,O$ . . .	493 "
Total, ...	2080 "

And for the calculated weight of fuel

199680 228800 274560 309920 cal.

Leaving the heat to pass off

97728 124080 165548 201001 cal.

The weight of $Ca\,O\,C\,O_2$ to be decomposed per hour is

164 188 226 255 kil.

and as it takes two hours to effect the operation at 1000°, the volume of it will have to be double,

.246 .285 .338 .382 sq. met.

The height of the chambers being one meter, their length, in order to contain these quantities, must be

.5 .6 .7 .8 met.,

and it will require two chambers in order that one may be working while the other is being charged.

The chambers containing the carbon for reducing the $C\,O_2$, which is given off by the lime, should be as large as practicable, in order to avoid the necessity for frequent charging, and allowing for height one meter, and breadth .25 met., we propose to give the lengths

1.2 1.5 1.4 1.5 met.,

and the following number of the chambers,

3 3 4 4

We have seen that the gas produced in the generators receives the temperature only of 295°, which is not enough to effect a perfect reduction, but by surrounding the generators with products of combustion at 1000°, we can effect a perfect, which is a matter of great importance. By making two generators .8 met. long, .8 high, and .45 wide, we can arrange them in the furnace with the necessary chambers, in such a manner that the latter will present a minimum surface of 15.97 sq. met., and a maximum of 20.66 sq. met., and allowing a thickness of wall of .5 met. $=e$, and a conductibility $c=.6$.

Then the theoretic transmission, per sq. met., per hour, will be

$$\frac{1000^\circ - 20}{1 + Q:\frac{5}{6}} + 20 \times 10.197,$$

and the actual transmission four or five times greater, ... = 5722 cal.

Total maximum transmission 2066×5722 . . } = 118216 "

Total minimum transmission 1597×5722 . . } = 91380 "

while the quantities at our disposal are, maximum, 201001 cal.; min. 97728 cal.

Hence the quantity of heat passing out of the fusion furnace is more than sufficient for the production of the carbonic oxide.

If the assumptions we have made as to the relative time of fusion are correct, which is very probable, the consumption of fuel for one kil. of steel will be

$$\frac{96 \times 8}{1552} = 0.495 \text{ k.} \quad \frac{110 \times 6.5}{1552} = 0.461 \text{ k.}$$

$$\frac{132 \times 5.5}{1552} = 0.425 \text{ k.} \quad \frac{149 \times 4.5}{1552} = 0.431 \text{ k.}$$

lignite, while by the furnace at Leoben it is

$$\frac{291 \times 8}{1552} = 1.5 \text{ k.}$$

Origin of Force—Weight no Force.—Gravitation, acting in the direct ratio of the mass of bodies, gives us a direct measure of this mass by the weight. As a unit of this weight the pound has been adopted, and the expression of a certain number of pounds affords us, therefore, a tolerably definite notion of the amount of matter with which we have to deal. When, now, by the removal of obstacles, gravitation is allowed to produce motion, this motion, must accelerate as long as gravitation continues to act in the direction in which the body is moving. The motion thus produced by gravitation is called an accelerated motion; but gravitation is not necessarily an accelerating force. It may act as a retarding force, when the body moves in an opposite direction, as, for instance, when a stone is thrown upward. In fact, gravitation may result in an accelerating force, in a retarding force, or (in case there is no opportunity for the body to be brought into motion) in no force at all.

But to return: a body is put in motion by gravitation only; it falls, and there is a force generated, which increases in proportion to the space through which the body falls. This space, again, is proportional to the square of the time that gravitation acts, according to the well-known law of falling bodies. Suppose, now, that this motion, after being produced by gravitation, is totally or partially destroyed by resistance, heat will be produced. Direct experiments have demonstrated this to be a permanent fact. By modifying the circumstances, electricity, light or magnetism may be produced or apparently generated; and we may therefore look upon gravitation as the prime source of all other forces. In the same manner as we cannot destroy the motion of a leaden ball, falling only from the height of a few feet on the floor, without observing a remarkable increase in the temperature, so any cosmical matter, falling toward a center of attraction (the sun), must, at reaching that center, where its motion is destroyed, cause a rise in temperature, of an intensity proportional to the weight of matter, and to its final velocity. When the masses are thousands of millions of tons, and the distance through which they fall thousands of millions of miles, and consequently the velocities enormously great, the resulting rise in temperature must necessarily be far beyond our conception. This is, in fact, the modern modification of the celebrated nebular theory of La Place.

When gravitation is prevented from producing motion, no equivalent of heat can be produced by the destruction of motion, as there is no motion; and, as all force can be expressed by an equivalent number of units of heat (one unit of heat being 770 units of force or foot-pounds), it becomes at once self-evident that the simple weight of bodies, as it can not be expressed in terms of heat, can not and must not be considered as expressing anything like a force. It must, therefore, not be used in a sense conveying the thought that a ponderable body of a certain weight can represent a force. The defective but common use of language, in mentioning forces of so many pounds, hundred-weights or tons, should give way to the more accurate ideas of modern science. Reform in this direction will be much easier than at first appears.—*American Journal of Mining.*

Hollow vs. Solid Shafting.—Hollow shafting, where large diameter is not objectionable, has long been in use, made generally of cast iron, and frequently used as a drum or continuous pulley for the reception of belts. Such a shaft was used in the "pistol shop" of Colt's factory before the destruction of the building by fire about four years ago, and a similar line may now be in use in the reconstructed building. This shaft was five hundred feet long and fifteen inches diameter, made of hollow cast-iron cylinders, connected with each other by a solid shaft or bearing at each end, resting in a box as a journal. The result was an almost continuous drum, of five hundred feet in length, from which belts led to the counter shafts of the machines, the speed of each machine being regulated by the diameter of the pulleys on the counter shafts. We have heard also of wrought iron pipes of only two inches diameter being used as shafting successfully.

Tredgold says that a round tube whose internal and external diameters are as seven to ten, respectively, has twice the lateral strength of a solid cylinder containing the same amount of material. A cylinder (solid) of cast iron, five inches diameter, has a transverse strength of 21,104 pounds, while one of eight inches diameter, containing the same cross sectional area of metal, has a transverse strength of no less than 45,416 pounds.

These facts would seem to show plainly the possibility of reducing the weight, materially, of shafting, without a diminution of its strength. The weight of shafting is a mass, the inertia of which must be overcome by the driving power, and in some cases the amount of power, otherwise useful, that is thus absorbed, is not less than twenty per cent. If by the use of lighter shafting this could be reduced only five per cent, the saving would be worth an effort. Shafting must be of sufficient diameter to sustain the weight of pulleys and the strain of belts without springing, but if the requisite stiffness—resistance to torsion and springing—can be obtained by hollow shafts of much less weight, not only is money saved in the first cost (shafting being furnished by the pound), but the continual expense in the absorption of unnecessary power in driving the unnecessary weight would also be prevented. That hollow shafting of wrought iron can be made cheaply is sufficiently apparent when we examine specimens of pipe used for various purposes. And not only would the first cost be less, but the ease of handling, owing to reduction in weight, would lessen the cost of turning, etc. Such shafting could also be easily oiled from the inside, which would seem to be the proper method.—*Scientific American.*

Hartmann's Locomotive Works.—Mr. Richard Hartmann has recently added to his large works at Chemnitz, Saxony, a locomotive erecting shop, with lines for thirty-five engines. This shop is 466 ft. long, and 120 ft. wide. The shop for lathes and machine tools, which has been some three or four years at work, is 450 ft. by 90 ft. Mr. Hartmann now employs 2,300 workmen. They are chiefly employed upon locomotives and machine tools. When the business in textile fabric machinery is fairly prosperous, 500 more workmen are employed.

WIRE ROPE TRANSPORT SYSTEM.

"Mechanics' Magazine."

A novel use of wire ropes has recently been patented and put into practice by Mr. Hodgson, C. E., having for its object the construction of light and cheap ways for the transport of mineral or agricultural produce in localities as yet unprovided with railways. Though a great number of cases exist in Great Britain to which it may be applied with advantage, the chief development of this method of carriage will probably take place in the colonies, and in other countries which stand in urgent need of light lines of some kind to convey their productions to the main arteries of inland communication, or to ports. The system may briefly be defined as a continuous development of the plan now not unusual in India, Australia, and in some mining districts, of bridging over a river or ravine by a single wire rope, by which, carried in a bucket suspended by a pulley, the necessary loads are transmitted from one point to another.

To accomplish the easy passing of the points of support necessary to carry out a continuous line of communication, and to provide for the distribution of the burden and the application of motive power, have been problems of no small difficulty; but, after experiments on a first trial length of half a mile, during the autumn of last year, these practical details were worked out, and a contract was immediately entered into for a line of three miles in length at Bardon Hill quarries, belonging to Messrs. Ellis and Everard, near Leicester, which has recently been completed, for mineral traffic. The practical working of this line was recently tested in the presence of a number of engineers and gentlemen interested in the question, when it was found to work well, and to answer its purpose admirably. This line consists of an endless wire rope, supported on a series of pulleys carried by substantial posts, which are ordinarily about 150 feet apart, but, where necessary, much longer spans are taken, in one case amounting to nearly 600 feet. This rope passes at one of its ends round a Fowler's clip drum, worked by an ordinary portable steam engine, and the rope is thus driven at a speed of from four to six miles an hour. The boxes in which the stone is carried are hung on to the rope at the loading end, the attachment consisting of a pendant of peculiar shape, which maintains the load in perfect equilibrium, and at the same time enables it to pass the supporting pulleys with ease.

Each of these boxes carries 1 cwt. of stone, and the delivery is at the rate of about 200 boxes or ten tons per hour for the three-mile distance. It is almost unnecessary to observe that the proportions of such lines can be varied to any extent to suit the requirements of any particular trade, ranging from 10 tons to 1,000 tons per day.

In the case of lines for heavy traffic, where a series of loads, necessarily not less than 5 cwt. to 10 cwt. each, must be carried, a pair of stationary supporting ropes, with an endless running rope for the motive power, will be employed, but the method of supporting, and the peculiar advantage of crossing almost any nature of country with a goods line without much more engineering work than is necessary for fixing an electric telegraph, without bridges, without embankments, and without masonry, exists equally in both branches of the system. The cost of establishing these lines will vary considerably in proportion to the quantity they are required to carry, but from their peculiar construction their cost will vary very slightly in relation to the nature of the ground which they may traverse.

The most important feature in Mr. Hodgson's invention is his method of passing the points of support. Both in lines like that now in operation, where the rope moves, and in those in which it is proposed to have a standing rope separate from the propeller, the stability of the load is obtained by curving in the frame of the carriage till the centre of gravity comes under the rope. The overhanging of the rope is of course essential in this case. Nothing can be more satisfactory than the working of the present three mile line, which stamps it as a practical invention, and which we hope will lead to its adoption wherever the necessity for such an appliance exists.

Burning Liquid Fuel.—Another system has been, after long experiment, put in regular and successful operation by Mr. A. Smith, Stratford, England. The creosote is stored in an underground tank outside the engine-house, from which it is forced up by steam pressure into a reservoir, also outside the engine-house, and to which is attached a float and a graduated scale, by which the consumption of oil is ascertained. A supply pipe from the cistern, with a regulating cock is turned into the tube of each of two

Cornish boilers, 18 ft. long, 5 ft. diameter, with flues 2 ft. 6 in. in diameter. The oil supply pipe projects about 9 in. into the boiler tube, the mouth of which is simply covered by a plate of thin sheet iron, which is raised or lowered to regulate the draft. Into the oil tube is turned a smaller tube carrying the superheated steam, which issues from small apertures at its nozzle. The creosote is thus driven into the furnace with great force, being broken up into the finest spray, and forming a powerful flame, which impinges upon a heap of brick core in the tube which is maintained at a red heat.

From the single jet, steam is easily kept in each of these boilers at a constant pressure of 55 lb. to 60 lb., which is supplied to two engines for driving the machinery. One of these engines is a 10-horse power horizontal; the other, a 30-horse power beam engine. Besides the two boilers already mentioned, there is a third of the same dimensions, in which steam is kept up by the waste and refuse produced in the factory, the steam being used only for heating purposes, and not for the engines. This boiler is always going, and in the morning supplies steam with which the creosote furnaces are started.

The consumption for the two boilers is seven barrels of thirty-six gallons each per day of 12 hours. Taking the cost at the fair price of 1d. per gallon, we have only £1 1s. per day, or 10s. 6s. for each boiler. Mr. Smith's consumption of coal used to be 2½ tons per day—a great contrast in point of expense to his present working. Then, there is a further saving in attendance, a boy being well able to do all that is necessary, whilst there is no clinkering, nor are there any fire-bars to burn out. Altogether, a great economy is realized, and much credit is due to Mr. Smith for the simplicity and efficiency of his invention.—*Mechanic's Magazine.*

THE "ZIRCONIA" LIGHT.—The specification of Messrs. Tessie du Motay & Co. for improvements in oxyhydrogen light, is as follows:

"Zirconia, or oxyd of zirconium, in whatever manner it may be extracted from its ores, can be agglomerated by compression; for example, into sticks, disks, cylinders, or other forms suitable for being exposed to the flame of mixtures of oxygen and hydrogen, without undergoing fusion or other alteration. Of all the known terrous oxyds, it is the only one which remains entirely unaltered when submitted to the action of a blowpipe fed by oxygen and hydrogen, or mixtures of oxygen with gaseous or liquid carbonated hydrogens. Zirconia is also, of all the terrous oxyds, that which, when introduced into an oxyhydrogen flame, develops the most intense and the most fixed light.

"To obtain zirconia in a commercial state I extract it from its native ores by transforming, by the action of chlorine in the presence of coal or charcoal, the silicate of zirconium into double chloride of zirconium and of silicium. The chloride of silicium, which is more volatile than the chloride of zirconium, is separated from the latter by the action of heat; the chloride of zirconium remaining is afterwards converted to the state of oxyd by any of the methods now used in chemistry. The zirconia thus obtained is first calcined, then moistened, and submitted in molds to the action of a press with or without the intervention of agglutinant substances, such as boracic acid or clay. The sticks, cylinders, disks, or other forms thus agglomerated, are brought to a high temperature, and thus receive a kind of tempering or preparing, the effect of which is to increase their density and molecular compactness.

"I can also compress in molds shaped for the purpose a small quantity of zirconium capable of forming a cylinder or piece of little thickness, which may be united by compression in the same mold to other refractory earths, such as magnesia and clay. In this manner I obtain sticks or pieces of which only the part exposed to the action of the flame is of pure zirconia, while the remaining portion which serves as a support to it is composed of a cheap material.

"The property possessed by zirconia of being at once the most infusible, the most unalterable, and the most luminous of all the chemical substances at present known when it is exposed to the action of an oxyhydrogen flame, has never before been discovered, nor has its property of being capable of agglomeration and molding, either separately or mixed, with a small portion of an agglutinant substance."—*Chemical News.*

NAVAL BUREAU OF STEAM ENGINEERING.—The appointment of Mr. King in place of Mr. Isherwood as chief of this department, will close the era of experiments, and inaugurate, it is to be hoped, the safe practice of following good examples.

BUTT-JOINTED BOILERS.

From "Engineering."

For some time past several of our leading locomotive engineers have been in the habit of making the boilers of the engines constructed by them with butt-jointed longitudinal seams, provided with both inside and outside covering strips. No doubt those employing this form of joint, consider it—and very justly—to be a good one ; but, judging from the proportions of the riveting frequently used in connection with it, we believe that in many cases its merits are far from being fully appreciated. Our reasons for this opinion may be explained very briefly. In the case of what we may term an "ordinary" riveted joint—as, for instance, a lap-joint, or a butt-joint with a covering strip on one side only—failing by the shearing of the rivets, this shearing takes place at one point only of the length of the latter, whilst in the event of a butt-joint with covering strips on both sides failing in a similar way, each rivet will be sheared at two points. In other words each rivet is in the last-mentioned joint in a state of "double shear," as it is sometimes called, and therefore exposes twice the resistance that a rivet of the same size would offer in, what we have termed for ditinction, an "ordinary" joint.

Taking this fact into consideration, it follows that in a butt-joint with covering strips on each side of it, the clear space between each pair of rivet holes, should for any given diameter of rivets be twice as great as an "ordinary" joint made with rivets of the same dimensions. Judging, as we have said, from the proportions of the riveted joints of the kind we are considering, which have been actually adopted in practice, the fact just stated has been very generally overlooked, and the rivets have been set at the same pitch as if they were in "single shear" only. Under these circumstances the strength of the rivets is very greatly in excess of that of the length of plate left between the rivet holes, and the joint is, therefore, to some considerable extent, weaker than it would be if proper proportions were adopted.

The actual extent to which the strength of a butt-joint with covering strips on both sides is deteriorated by the adoption of a pitch of rivets, etc., suitable for "ordinary" joints, depends upon other considerations besides the one already mentioned, and how this is the case, we can perhaps best explain by an example. Let us, for instance, suppose a boiler, composed of $\frac{1}{2}$ in. plates, and having butt-joints with covering strips on each side, has been riveted up with $\frac{7}{8}$ in. rivets placed at 2 in. pitch—a proportion very commonly adopted in locomotive work—and let us see how far the strength of the joint can be increased by taking into consideration the fact that the rivets are in "double shear." In doing this we shall preserve the proportion between the areas of the rivets and of the plates between the holes unaltered—not that we consider it the best, however—and we shall suppose the strength of the joint to bear the same proportion to the strength of the solid plate as the length of the plate left between each pair of rivet holes does to the pitch between the centers of those holes. We are quite aware that this latter supposition is not exactly correct; but in comparing several joints with each other the error arising from the adoption of such a standard of comparison is very light. Having made these premises we may now return to our proposed investigation. In the case of the joints with $\frac{7}{8}$ in. rivets placed at 2 in. pitch, the length of plate left between each pair of rivet holes would be $1\frac{1}{8}$ in., or nine-sixteenths of the pitch, and the strength of the joint, measured according to our standard, would be nine-sixteenths, or $56\frac{1}{4}$ per cent. of that of the solid plate. Acting on the consideration that the rivets are in double shear, they might theoretically be moved to a distance of $3\frac{1}{8}$ in. apart from center to center, leaving a space of $2\frac{1}{4}$ in. between the holes, and increasing the strength of the joint, measured, as before, to eighteen-twenty-fifths, or 72 per cent. of the solid plate. If a pitch of $3\frac{1}{8}$ in. was admissible with rivets $\frac{7}{8}$ in. in diameter, we should, as will be seen, then obtain an increase in the strength of the joint equal to $15\frac{3}{4}$ per cent. ; but practically it would be impossible to keep such a joint tight under high-pressure steam, and we therefore come to the conclusion that in place of increasing the pitch it will be advisable to reduce the size of the rivets in order to allow for the latter being in double shear. Let us, for instance, allow the distance between the rivet holes to remain $1\frac{1}{8}$ in. ; and let us employ rivets $\frac{5}{8}$ in. in diameter in place of $\frac{7}{8}$ in., the area of the former being practically half that of the latter. Under these circumstances the pitch will be $1\frac{1}{8} + \frac{5}{8} = 1\frac{3}{4}$ in., and the length of the piece of plate left between each pair of rivet holes will be nine-fourteenths of the pitch, the strength of the joint being thus, according to our standard, nine-fourteenths, or 64.285 per cent of that of the solid plate. The gain over the strength of the joint with $\frac{7}{8}$ in. rivets and 2 in. pitch, is not so great in this instance as when the space between the rivet holes was doubled; but it nevertheless amounts to over 8 per cent—an increase well worth gaining.

We have, we think, said sufficient to explain the principles which we consider should be borne in mind in determining the proportions of riveting for butt-joints with double covering strips, and we need not, therefore, say more about these principles here; but before leaving the subject it may be interesting to point out a deduction to which the facts above stated lead. This deduction is that a properly proportioned single-riveted butt-joint, with any given thickness of plates, and with covering strips on each side, possesses nearly the same strength as a properly proportioned double-riveted lap-joint or butt-joint with a covering strip on one side only. In a properly proportioned double-riveted joint the spaces between the rivet holes (measured along each line of rivets, not zigzag) should be twice as great as that required in single riveted joints having rivets of the same diameter; and we have seen that the same rule applies to single-riveted butt-joints with double covering strips, hence our deduction. In a double-riveted butt-joint, with covering strips on both sides, the strength bears, of course, the same proportion to a single-riveted joint of a similar class that a double-riveted "ordinary" joint does to a single-riveted one.

In concluding this article we may notice one matter connected with riveted joints to which attention is not generally paid, and that is that the proportion which the strength of the joint bears to the solid plate increases with an increase in the diameter of the rivets used. The reason for this is self-evident. The area of rivet increases as the square of the diameter, whereas the length of plate (measured along the line of the joint) removed to make room for the rivet varies as the diameter of the latter only. Thus, supposing that with a certain thickness of plates $\frac{7}{8}$ in. rivets should be placed at a pitch of 2 in., leaving $1\frac{1}{8}$ in. between the holes, then, with the same thickness of plates, $1\frac{3}{4}$ in. rivets (supposing the use of such rivets was admissible) would have to be placed at a pitch of $6\frac{1}{4}$ in., the spaces left between the holes being $4\frac{1}{2}$ in. In the former case $43\frac{3}{4}$ per cent, and in the latter case but 28 per cent of the plates would be removed in forming the rivet holes. This fact shows that it is desirable to in all cases employ in riveted joints the largest diameter of rivets consistent with the fulfilment of other requirements, which practice has shown to be necessary for the attainment of good results.

UNDERGROUND RAILWAYS.

THE DIFFERENT SYSTEMS COMPARED.

The Metropolitan Underground Railway, in London, is the model, from which any departure would be, according to the majority of newspaper reports, presumptuous, unsafe, and not to be considered. We propose to review very briefly the various reports relative to this line, and the opinions of engineers upon it, with a view to give some light to those who take an interest in the subject as it affects New York and other American cities.

The accounts of the success of that work, published here, appear to have emanated from the promoters of various schemes of the kind for New York, and are more favorable than those we find in English engineering journals. For example: in a pamphlet on the Arcade Railway scheme is an extract from the "Evening Post," purporting to be from a report of an eminent American engineer, stating that the work is a great commercial success, and that, though it cost enormously, its dividends have been 12 and 15 per cent. But in the "Railway News" we find that the dividends have been 5 per cent for the first year, $5\frac{1}{2}$ per annum for the next half year, and 7 per cent from that time to the last half yearly dividend, which was at the rate of $5\frac{1}{2}$ per annum. And we find that there has been a serious controversy, in which the directors have been charged with impropriety in making dividends out of capital. A public accountant, Mr. J. P. Lithyre, in a pamphlet, says he was requested, professionally, to examine and report upon the affairs of the company, and that he found that the dividends had been paid mainly out of capital; and that the earnings had not been much over 2 per cent; and that, after closing the capital account, it would be a considerable time before the common stock would receive 3 per cent dividends.

We also see a report that another underground line, in London, from the post-office under Holborn and Oxford street, is projected, to be worked by stationary engines. This indicates that the system of the Metropolitan line does not fully satisfy engineers. "Engineering," though it highly lauds the construction, rolling stock, and working of the Metropolitan, has speculated on improvements which would involve a general reconstruction, or something nearly equivalent.

And there are other systems, which for some years have been discussed, which imply that the Metropolitan is not the best system for city passenger traffic, however fit it may be for the work of the Great Western railway, for which it was built,—being an extension of that line into the heart of the city. Of these proposed systems, that of Mr. P. W. Barlow, has found most favor. Its main features are: 1st. Stations on summits, thirty feet or more above the general level of the line. 2d. Starting the trains from the stations, by very powerful stationary engines, at speed sufficient to send them to the next station. "Engineering" decidedly approves the summits, even for lines worked by locomotives.

Of the plans proposed here, which have been before the Legislature, the first conceived was that brought before the Legislature by Mr. Schuyler, two or three years ago. It was published in 1852, in "Appleton's Mechanics' Magazine," by W——n, (whom we take to be Mr. Worthen, C. E., then attached to the New Haven railway.) Its chief object was, to bring down to the lower part of the city the cars of the New Haven and other country lines; but it also had a secondary object, which was, the city passenger traffic. These objects are the same as those of the London line; and, had the plan been adopted here, probably it would have resulted, as there, in a success of the subordinate object, to such extent as to embarrass the chief object. This plan was, to run a double track railway, in an open cutting between Broadway and Mercer, and other streets in line. Since that time it has become much more difficult, on account of the buildings that have been put up on the rears of the lots; some of which have cost highly, and would greatly enhance the land damages.

Mr. Willson, at first, actively proposed the underground line in New York, after examining fully into the London line, and Mr. A. P. Robinson, C. E., who assisted him, were inclined to propose this route between streets, as much as possible, in open cuttings; but were constrained, by the prospect of enormous land damages, to propose a tunnel under Broadway. And the other underground plans, including the Arcade, have the same feature of being entirely covered, therein differing from the Metropolitan, which is one-third in open cuttings. Messrs. Willson and Robinson propose to ventilate through hollow lamp posts fourteen inches in diameter; and the Arcade is proposed to be ventilated trough the areas of the buildings. We do not believe that either plan of ventilation would render the air wholesome or endurable; and the ventilation through the areas would vitiate the air in the buildings, especially when the windows are open. Neither plan would work so well as that of the Metropolitan; and that excites much complaint, and though its friends are reticent about it in public, they privately admit that it is far from satisfactory. Mr. Johnson, its resident engineer, while in this city, said that the company intended to buy more land to make more openings; and Mr. Dredge, an engineer, who was employed in the construction, informed us that, twenty feet inside the tunnels, the sulphurous odor of the gases was perceptible. And there have been reports in the journals that the health of the employees has been seriously impaired, and several passengers have died on the line. Compared with the open cutting plan, this plan is so inferior that no just amount of land damages can warrant its adoption, if we may judge from the evidence that has come under our notice; and the close tunnel and arcade plans, we believe, would be so much worse that locomotives could not be used in them without repelling the greater part of the people for whose use the work is proposed.

There have been other plans, but as they seem not likely to get moneyed backers, or to be further urged, we have no occasion to seek for their faults, and we know of no merits in them that require us to notice them particularly.

These tunnels would have a different character could they be worked by stationary engines, either on the rope-traction system, or on Barlow's system of impulsion. The rope system has not yet got beyond a very feeble infancy, totally inadequate to the service required in this city. That of Barlow has not been even tried, but it looks well in theory. And, compared with the open cutting plan, for the line between Broadway and Mercer street, we think, in view of the land damages, that Barlow's system is not unlikely to be deemed best, after full consideration of the advantages and disadvantages of both plans.

Barlow represents—in papers read before the Society of Civil Engineers—that the cost of the permanent way will be much lessened if the 42-ton locomotives can be got rid of. It is commonly held that a 4-coupled locomotive of this class injures the track fully as much as twice its weight of carriages; and, as the trains weigh but 80 tons, it follows that more than half the cost of track is by the engines. And this wear is such, that the steel rails have to be renewed in two years. He also represents that the cost of stationary engines would be much less than that of locomotives. And fuel of ordinary quality could be used, instead of the best coke, at double the cost of coal. But the most striking advantage claimed is a considerably higher speed; the stationary engine, drawing by means of a chain, is not limited in power like the locomotive, by liability to slip, but may draw with a force equal to the weight of the train, or greater; whereas, the Metropolitan engines draw with a force not exceeding $\frac{1}{35}$th of the weight of the train and engine. Therefore, in a thirty-fifth of the distance between stations, the stationary engine *may* do as much work as the locomotive can do in the whole distance. And practically, there is no doubt, a stationary engine, working with a chain over two pulleys two hundred feet apart, may start a car or a train with sufficient speed to overcome all the resistances on a line of half a mile, and arrive at the next station at a useful speed of six miles an hour or more. The descent from the summit will help to give the speed; and the ascent to the next summit will help to extinguish it, or will reduce it to a low rate, which the brakes will extinguish without much wear of wheels.

To explain this, let us suppose an excessive undulation of the line. Let the stations be on a level with the sidewalks, so that the passengers need not have the fatigue of going down and up stairs, for twenty feet average as proposed by the tunnel projectors, or seventeen feet as proposed by the arcade people. From these stations let the line descend both ways, at the rate of 1 in 5, for 660 feet. In running down this incline, a car will acquire a speed of 60 miles an hour; it will not only overcome the inertia of its weight, but will also overcome the additional inertia of its wheels and axles as rotating bodies. It will then continue to run, on a level, at 60 miles an hour, until it reaches the next incline, which it will ascend, and arrive at the summit with its speed extinguished. In this case we suppose that it has had no friction or atmospheric resistance, or that these resistances have been overcome by additional power given by the stationary engine. Thus the power required to start is given by gravitation, and taken back by gravitation; and only the power necessary to overcome the resistances of steady running has to be given by the fuel, with a small addition for an excess of speed of six miles an hour, at the end of each run, to save time.

In this mere illustration we have supposed an inclined plane from the summit, and a level to the next incline; but Mr. Barlow proposes a cycloidal curve from summit to summit, as the line of quickest transit.

In the descent, on the inclined plane, the car would run an eighth of a mile at an average speed of thirty miles an hour, and would then run a quarter of a mile at the rate of sixty miles an hour, and then ascend the next incline at an average of thirty miles an hour, making three-quarters of a minute for the half mile. It would then stop three-quarters of a minute—which is the time on the Metropolitan—making one and a half minutes, or three minutes per mile, or an average speed of twenty miles an hour, with stations one-half mile apart. Now "Engineering" computes that $13\frac{3}{4}$ miles an hour is the highest speed practicable on the Metropolitan system, with stations five-eighths of a mile apart. Thus it seems that, without exceeding the maximum speed obtained on English railways—64 to 75 miles an hour—we can get an average speed one-half greater by Barlow's system than we can get by the Metropolitan system, or the modifications of it proposed here.

Comparing the plan of Mr. Schuyler or Mr. Worthen with the tunnel or arcade, we find certain advantages in each. As to speed, it will be greatest where steam can be made most freely, that is, in the cuttings. In the tunnels, on the Metropolitan, the exhaust is turned into a condenser; and not more than one-eighth as much steam is made as is made in the cuttings, where the blast is used. And here, we are confident, the covered ways will prohibit rapid steaming;

and high speed will be attained only in the open cuttings. On the other hand, the covered line will be protected from atmospheric influences, which will render a better construction practicable, and insure greater durability, and get rid of the troubles due to snow and ice, and the cost of removing them. This advantage will be most fully attained in Barlow's plan; for that admits of being entirely housed, covered, and ventilated by the best methods; so that the temperature need not vary beyond the limits of 60° in winter, and 80° in summer. The permanent way may, therefore, be uncommonly permanent; but whether the air will be pure enough for health and comfort is a more doubtful question, which may be answered, more or less confidently, by those who are accustomed to ferry boats, city cars, and other conveyances controlled by men who have got their franchises by favor or otherwise, and use them solely to gain all they can by them. In view of such uncertainties, the open cutting will have numerous advocates.

A station on the Barlow plan will occupy the lower story of nearly the whole rear of a block, for a width of 30 feet; but it may be built over, to any height, by those who supply dark offices to people who are so improvident as to use them. From this block the line will descend so rapidly as to go under other blocks, without disturbing them—the tunnels being driven. The land damages will therefore not much exceed the cost of land for the stations.

The cutting plan will occupy at least 28 feet wide through the back yards. This, or even 40 feet, would really be no loss to the property, for the light-room would be worth more than the buildings that could be put upon it; but this is not the opinion of land owners, and they would demand, and probably get, immense damages—perhaps so much as to render the work unproductive.

There is another plan proposed in a paper on underground railways, read before the Polytechnic Club of the American Institute, by Mr. J. K. Fisher. He proposes to adopt the open cutting plan, locating it where land damages may be less than on the line between Broadway and Mercer street; and to modify it by laying an iron floor instead of rails, and by running steam carriages instead of trains drawn by locomotives. He claims that the carriages can pass each other, so that through carriages can run from end to end without stopping, at full speed; and that the speed may be greater than is attainable on rails, because the flange and cone friction will be avoided. For an up-and-down line 40 feet width would be required; and a guard in the middle, to keep down-carriages from meeting up-carriages, might be adopted; so that collisions could occur only by carriages overtaking others, and the violence would be in proportion to the difference of their speed, and not so great as to cause injury to persons. But when two streets of this kind are built, one may be used for upward, and the other for downward carriages, and the guard may be removed. No pedestrians, and no vehicles but those of the company, to be allowed in these undergrade streets; and all vehicles to run at one rate of speed when on the middle of the street; and to turn out before they stop. The stations may be nearer together than on a railway; and the way-carriages may pass some of them, so as to make fewer stops than trains must make; for example: Carriage A, starting from station 1, may stop at station 3, 5, 7, etc., or at 4, 7, 10, etc.; and carriage B may stop at intermediate stations, so that passengers will be better accommodated, and the speed will be less interrupted than on rails, where every passenger must stop at every station.

Steam carriages are under a cloud, which their friends regard as a cloud of ignorance. They were designed for common roads, and ran upon them to the extent of 50,000 miles or more, before railways got much into use. They were practically approved by several of the best mechanical engineers in the world, who took out patents for improvements in them, and built them. Among these engineers were Maudsley, Field, and Richard Roberts, then at the head of their profession; and Scott Russell and W. A. Summers, then rising to celebrity. But the iron road beat the macadam road; and the locomotive, then called a steam carriage, was supposed to have beaten a lighter steam carriage; but there was powerful opposition to both systems of steam locomotion, against which the common road carriages did not prevail. But about twenty years ago Mr. Brydges Adams proposed steam carriages for railways, and built several, which worked well where the traffic was insufficient for trains. In this country we call them steam cars, and have used them, and still use them, to a considerable extent; and Mr. A. P. Robinson, in his report of a plan for a tunnel railway under Broadway, proposes to adopt them exclusively for that line; and gives engravings of two plans, one by Grice and Long, the other by Mr. Fisher. Take the flanges from their wheels, and add steering gear, and these cars become steam carriages capable of running on any good road. It is supposed that they cannot run profitably on a poor road; but none who have examined them doubt that on iron or even stone floors they can work advantageously.

The question, therefore, is: can light engines, on equally good roads, with stations half a mile apart, work more economically than heavy engines? Can 125 tons be stopped and started as cheaply as ten tons, or less? Mr. Robert Fairlie, C. E., distinguished as the inventor of a new locomotive that is coming much into use, has shown, in a paper read before the Society of Engineers, that the average number of passengers, per train, on the Metropolitan railway is 55. A 10-ton carriage could carry them; and most of the work done in the middle of the day could be done by a few light carriages, leaving the greater number at rest until the movement of people to and from their business. Not only is an unnecessary weight of train used for a small traffic during a great part of the day; but this weight stops and starts at all stations, and cannot do otherwise on this system. Now, on several of our railways, whose maximum speed is not much greater than that on the Metropolitan, careful observations have been made, to find the cost of stopping and starting trains; and they agree, very nearly, that one cent per ton is about the cost. Mr. A. F. Smith, ten years ago, when superintendent of the Hudson River railway, estimated that it cost $1.25 to stop and start a passenger train on that line, on which the trains averaged about 125 tons. Now there is an advantage in favor of a steam carriage, in that it can stop by reversing, and thus avoid wear of its wheels by brakes; and this advantage, where stops are frequent, goes far to balance the greater economy of large engines, so that it is not extravagant to say that one cent per ton would pay for stopping and starting it, and that this considerable part of the working expenses will be lessened in proportion as the weight to be stopped is lessened. But as the through carriages will make but few stops, and the way carriages will stop less than the trains, there will be further reduction on this score. Moreover, if a single carriage breaks down, it will slide along on a floor, and no person will be hurt; but if a locomotive, or a car in a train, break down, all that follows will dash against it, and many may be killed and wounded. Therefore it is necessary to make the railway vehicles excessively strong and heavy for safety. The cars on the Metropolitan weigh sixteen tons empty. Half this weight could be saved were they not subject to be strained by the 42-ton engines, and were there no serious harm to come in case of breaking down.

Considering all these conditions, it is probable that eight times more fuel is consumed on the Metropolitan railway, for an equal number of passengers carried, than would be consumed on an iron floor by steam carriages; and that this consumption of fuel is an approximate index of the wear and tear of engines and carriages.

All these schemes should be tested, so far as practicable, before risking a vast capital upon any of them. The cost of testing the economy of either of the railway plans would be great,—miles must be built and worked for some time before a reliable judgment could be formed. But to test the unsettled questions relative to steam carriages, whether they can be steered securely at the speeds desired, and can work effectively and economically, would involve little cost, for one may be tried on any good macadam road. A very large boiler would be required to test the practicability of steering and handling, at high speed, on a common road; but this would be allowed for in estimating the useful load that may be carried on an iron floor.

In this plan the way traffic will not retard the through traffic, nor the intermediate traffic, but each carriage will run at as high a speed as if it had the whole road to itself. A carriage that loads at the Battery and unloads at Harlem, will run through at full speed; and one that stops at two or three stations below Canal street, to pick up passengers, will run eight miles at full speed, and then stop at two or three stations to set them down and pick up others. And the short traffic, by alternate carriages stopping, will be made somewhat speedier than it can be on rails.

The tractive force of the locomotive is relatively small—30 tons on the drivers to 125 tons total weight; but the steam carriages will have twelve tons on the drivers to 20 tons total weight; its power to start quickly will, therefore, be greater in the proportion of two and a-half to one; and this would enable it to attain a considerably higher average speed on the short traffic. It is understood that on long runs the speed is due to the boiler; but on short runs it is due, in a great measure, to the cylinders, since they get up the speed. Mr. Fisher claims that sixteen miles an hour may be got on the short traffic, and 40 on the through traffic, and intermediate rates on the intermediate traffic, according to the frequency of stops; and these rates will not tax the engines or the way more than they are taxed in English foot passenger practice, or on the Metropolitan railway.

Having thus compared the Barlow tunnel plan with the open cutting plan, worked in two different ways, and shown that the speeds probably will be, for the railway in the cutting, thirteen and three-quarters at the utmost, and for the floor, sixteen to 40, and in the Barlow tunnel it may be 20; we may briefly consider the speed of the rope-traction tunnel plan which Mr. Hawkshaw proposes to go under Holborn and Oxford street. The wire rope is to run all the time at sixteen miles an hour, and the cars are to have means of "slipping the rope," which, we presume, means that they are to catch hold of it in such wise that there will be some kind of yielding, that the car may start gradually. Mr. Harvey, on the Greenwich street elevated railway, has springs on his cars, which are bent by the rope to soften the shock, and to avoid loss of power by friction. But this plan does not work well even at eight miles an hour; and the rope system on the Blackwall railway did not do what is required for the lines now proposed; and we know nothing of Mr. Hawkshaw's new devices, if he has any; and though we don't venture to say what can't be done, we say that the rope system has had a long trial, under the Stephensons, and failed to equal the locomotive; and it must be farther improved before it will equal the plans we have herein set forth at some length, but not fully. But we will suppose, for the comparison, that Mr. Hawkshaw has devised means to take hold of the running rope without wearing it, and to start his car gently, and to do all he requires in this detail. What, then, is to be his speed? It will be liberal to take only one mile from his sixteen for the half speed, while the cars are stopping and starting every half mile. It will require, then, two minutes to run half a mile, and three-quarters of a minute stopping, which is five and one-half minutes per mile, or less than eleven miles per hour average speed. This is about what "Engineering" estimates for a line like the Metropolitan, if its stations were only half a mile apart; and we suspect that Mr. Hawkshaw has aimed merely to equal the speed of that system, and that he has found no encouragement to aim at more.

Which system, then, is wanted? Speed, we presume, is the chief object in the estimation of the customers, who are ultimately to pay for the work. Fresh air is also growing into favor, to such an extent as to mitigate the objection that it would cost considerably to keep the open way free from snow and ice. These two requisites, speed and air, will be most surely found in the cutting. But they must be paid for in land damages, etc. The other plan, that of Barlow, is very comfortable in theory; but in practice we should expect more or less foul air, not to mention want of daylight. And the average speed may be set down at a third less than that on the iron floor. But Mr. Barlow estimates that the running expenses will be small compared with locomotive expenses. Into these estimates we are not prepared to go, and we find no careful estimates in our cotemporary journals.

Having given the gist of all we find worth reporting in the journals and other records, we might stop; but there is a modifying power which often overrules the opinions and even the experience of engineers, and which is very likely to derange such matters in this city. Lobbiers go to the Legislature and buy franchises to sell. These lobbiers know nothing of engineering; they take what has been succesful elsewhere; they exaggerate its success; they get up companies; they bull their stock and water it, and sell it; their job is then completed. And it is good luck if the plan they have established is not a bad one, made worse by being put in a place for which it was not designed. It may have on it the names of engineers; but engineers, like lawyers and other advocates, look out for fees. As one has little faith in a lawyer whom he does not pay himself, so he may about as well look out for engineers whom he does not pay. Not that engineers are less honest than other professional men; but, like others, they are of all sorts; some will resign their employments rather than betray stockholders, or swindle the public; others will hesitate, etc. But any set of lobbiers can get engineers enough to engineer any plan that is already "a success," though there may be better plans, which, whenever set to work, will underwork and render profitless the plans which are thus far successful, only because they have only old and worse plans to compete with. And we suggest to city men, who want these improvements, and intend to take and hold stock in them, that they would do well to employ engineers, on their own account, to get up plans, rather than buy the franchises which lobbiers have got from the Legislature.

In conclusion, we judge from the somewhat vague evidence, that the success of the Metropolitan railway has been greatly exaggerated; that the plan is deemed defective by many, if not most engineers; that it was not planned for the use into which it has unexpectedly fallen; that there are better plans for city traffic; and that it is not at all fit to go under streets where there cannot be openings enough to allow the steam blast, at regular intervals, for at least a third of the way. And, finally, that it cannot be applied in this city so usefully as either of the other plans which we have reported.

In these comparisons we have supposed the highest speeds that can be attained as about equal to what is practiced on the Metropolitan railway. It may be thought that the speeds should be less, so that the expenses and fares may be less. But the time of 55 passengers, for the 4.8 minutes required to go a mile, is worth $2.64, at one cent per minute per person, which is a low average for business men. And this high cost of time ought to be lessened. But those who do not appreciate this economy may assume any lower rate of speed, attended by less wear and tear, and by lower fares. And the saving will be as great in one system as in another, so far as we can now judge; and the comparison which we have made for high speed will hold good for any lower rate that may be acceptable to passengers, and profitable to the carrier.

A Gunpowder Pile-driver was described at a late meeting of the Franklin Institute. It resembles the ordinary pile-driver, except that a charge of powder is exploded, whereby the weight is forced up, where it is caught, till another charge is inserted. A 400-pound hammer can be operated with musket charges, driving the piles quicker and better than the ordinary pile-driver.

IRON ARCHED BRIDGES.

From a paper before the Société des Ingénieurs Civils, by M. Yvon-Villarceau, on the application of his theory of arches to the building of iron bridges.

For several years cast iron has successfully taken the place of wrought iron in iron bridges, with the exception of tubular and suspension bridges. The difference in the cost of wrought and cast iron is not the only reason of this change. In fact, if cast iron offers as much resistance as wrought to compression, it is quite different as regards tension, and it is known that engineers reckon little on the resistance of cast iron when undergoing strains of this nature; they then prefer to use wrought iron, which allows them to obtain much smaller sections than they could if they employed cast iron. The possibility will thus be perceived, in employing wrought iron, of reducing the building expenses of iron bridges where the metal offers resistance to tensile strains. But in supposing it possible to obtain, in this manner, a certain economy, there would be, by that very fact, a reduction in the mass of the construction: a consequence of this reduction of the mass is a diminution in the stability, because it is highly important that the bulk of vehicles and casual weights be as small as possible in relation to that of the construction itself. Finally, the theory of iron bridges, where, at certain points, the metal offers resistance to tension, and at others to compression, is not yet established, and engineers, obliged to have recourse to experience, prudently avoid extending the results to buildings of different dimensions from those they have already tested.

Cast iron bridges do not offer the same drawbacks. They may be so arranged that the metal will only have to resist compression, and the low price of the metal allows a lesser economy of the bulk employed. These motives seem to sufficiently explain the preference given at the present day to the use of cast iron in the building of bridges.

Let us now attempt to show how our theory of arches may be applied to the building of cast iron bridges. An arch of a cast iron bridge comprises three distinct parts. Firstly, the roadway and superstructure; secondly, the cast iron framing comprised between the floor and the extrados, and equivalent to the stone work of stone bridges; and, thirdly, the arch or assemblage of framing, analogous to the voussoirs of stone bridges, and which will fill the place of these latter. It will be first remarked that the framing of the system equivalent to the stone work is in the shape of hollow prisms with a vertical axis, ended at the upper part by an horizontal plane, and at the lower part by a curved surface in contact with the extrados of the arch. This arrangement of prisms agrees the more exactly with what we considered in our paper on the building of arches of bridges when their parts parallel to the road are more limited. The objections raised by some persons against the theory of normal action at the extrados in stone bridges could not be applied in this case, so that that theory may be said to apply more exactly to cast iron than to stone bridges.

The transition of the theory of stone bridges to cast iron bridges may be made in the following manner. Let us consider one of the vertical prisms forming the bulk of the bridge, and let us compare its weight with the weight of this prism. When considered as solid, we will deduce therefore the weight of the unity of volume, or the density of this prism. The first condition to be fulfilled is the coincidence of the actual center of gravity of the prism, and of that of the prism when solid ; the second is that all the prisms have the same density in the whole of the construction.

These two conditions are easily filled ; it would suffice to obtain the figure of the resulting internal space. Let us pass on to the framing constituting the voussoirs ; their density would be obtained in the same manner as for the other prisms, and we will obtain at once the same conditions as regards the equality of density and the position of the center of gravity. If the theoretical conditions are to be rigorously carried out, there would remain to reduce on the intrados, the surface of contact of the voussoirs on the small space which separates the actual and imaginary intrados.*

There remains to be examined the question of pressure. In the whole extent of the structure, considered as filled, the pressures are equal to those produced by a liquid, the density of which would be equal to that of the structure, and the upper surface of which would be loaded with a weight equal to that of the roadway and superstructure ; consequently, the pressures transmitted by the structure on the vertical sides which form its boundaries act horizontally, and the pressures received by the extrados are normal at its surface. To pass from these pressures, estimated on the hypothesis of continuous surfaces, such as those of the prisms or stone voussoirs, to those which answer to the case of prisms or hollow cast iron voussoirs, it evidently suffices to multiply the first by the relation of the surfaces which are in contact with the filled (solid) system with the corresponding surfaces of the hollow system.

It is evident that in the cast iron prisms or voussoirs the only surfaces of contact to be taken into consideration, are those capable of effectually transmitting pressures. (For instance, no notice ought to be taken of the surfaces of the cross bars used solely for forming connections in the direction of the axis of the arch.) The pressures thus obtained ought not to exceed a previously determined limit. Let us add that it would be always possible to render the pressures constant on each unit of surface—the whole extent of the arch, because, within large limits, the surfaces of contact are to be disposed of.

In stone bridges subjected to the conditions of stability we have laid down, if we have given us the opening of the arches, and the ordinates of the summit of the intrados, and of the springing lines in relation

* The theoretical conditions might be realized without touching the joints, by giving to the arch a constant thickness, e, which would render the extrados and intrados perfectly parallel to each other. For this purpose let $\tilde{\omega}$ be the weight of the unity of volume of the voussoirs, as previously defined, and $\tilde{\omega}'$ a variable density, according to the formula

$$\tilde{\omega}' = \tilde{\omega}\left(1 + \frac{1}{6}\frac{e}{\rho}\right),$$

in which ρ represents the radius of the curve ; the space of the voussoirs would be got rid of to realize the density $\tilde{\omega}'$ relatively to each by fixing the center of gravity at the point determined by theory, and the pressures could nevertheless be calculated in retaining in the general formulæ the quantity $\tilde{\omega}$.

In this case the actual intrados would be confounded with the imaginary one, of which it would suffice to consider the co-ordinates.

Preference, it appears, ought, however, not to be given to this solution ; it is better, in fact, not to extend the contact of bodies undergoing considerable pressures to the extreme limits of the flat surfaces of contact. On the other hand, we are accustomed to see the thickness of arches increase towards the springing line, and the effect upon the eye is generally pleasing.

to the horizontal plane which forms the limit of the surcharge, it will be found that the section of the intrados is nearly determined, independently of the thickness of the keystone, and the result is all the more exact when the densities of the materials of the surcharge and of the arch are the nearer equal. The whole bulk of the structure being then sensibly constant, the stability increases more rapidly than in proportion to the thickness of the arch, because it would be in proportion to this thickness if the mean pressure per unity of surface were constant, and this mean pressure decreases in inverse ratio to the thickness of the arch. As regards stability, it would therefore be better to increase the thickness of the keystone until there would be above it but the strictly necessary thickness of overcharge. This is not always done, and the reason is evident, because the price of a cubic meter of stone, cut and dressed as voussoirs, exceeds to an enormous extent that of filling up materials. In cast iron bridges, where a similar disproportion does not exist, there is nothing to prevent the arch from having the complete thickness demanded by a design. In the previous reasoning it is supposed that the casual overcharges result usually in increasing the pressures in the joints, so that it is to the interest of the engineer to diminish those which show themselves in the absence of any overcharge. When we consider the chances of decrease in the pressures, such as those which would result from slight motion of the soil, or sinking of the piles, one is lead to avoid reducing too low the pressures corresponding to the normal state of the arch. But if it be remarked that the casual surcharges are for cast iron bridges in a greater relation with the bulk of the structure than for stone bridges, this circumstance would be a motive for reducing the normal charges of cast iron bridges. Besides the connections made between the framework by bolts, present, to ward off cases when the casual pressures would fall a few points below zero, advantages incommensurably superior to those that could be expected from the cohesion of the mortar in stone work.

Let us finally add that if, without increase of expenses, it can be so arranged that the densities of the structure and voussoirs, understood as we have before said, be equal, the calculations to be done will be sensibly abridged, either directly or by means of special tables.

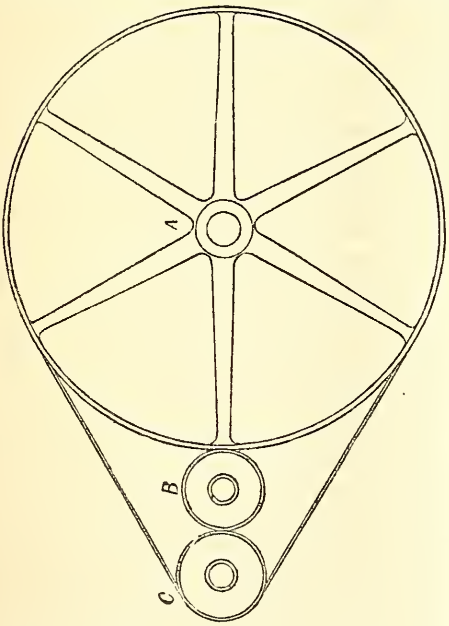
A New Steel-Headed Rail. — The "Engineer," after pointing out the various defects of welding steel slabs upon rail piles, expresses great confidence in the new (?) process of Mr. E. Gray, of Sheffield, which it describes and illustrates at length. The process is simply *casting* a steel slab upon an iron pile. The iron pile is heated and set in an ingot mould, but it does not fill the ingot mould; a space, say one to two inches wide, is left at one side, into which liquid steel is poured. The steel is expected to unite perfectly with the iron. The whole is then rolled into a rail, the steel surface forming the head.

We do not think this process, as described, can be relied upon, but that some radically new means and apparatus must be developed for overcoming the many practical difficulties. Our reason for thinking so is, that we have tried this plan without constant success—indeed with very uncertain and variable results. We have heated and set up in ingot moulds, iron slabs and blooms for rails, and iron cores for axles. Liquid steel poured into the mould would fuse and soundly weld to such parts of the iron as were *clean* and very hot. The practical difficulty is in getting out of a furnace, and setting up and centering in a mould, a heavy mass of iron, with such celerity that the surface shall not become much cooled and oxydised. Another more serious difficulty occurs in the case of casting a mere surface of steel upon an iron pile or bloom. If the iron bloom is made to perfectly fit the mould on the three sides not to be covered with steel, it cannot be got into the mould hot—the operation takes too long. If the iron bloom does not perfectly fit the mould, the steel will run all around it in thin fins, which have not mass enough to hold their heat and weld uniformly. The three sides of the resulting ingot, intended to have iron surfaces, have, in fact, facings of steel, partly welded and partly chilled upon the iron. When such an ingot is rolled it is sure to crack in the flanges, and to make a rough, bad rail.

We have also made several hundred rails by setting up heated iron or steel rail ends in the center of a mould, and casting steel around them. The mass of liquid steel being so thick, and the mass of the core being so small, a good weld generally resulted, but *not always*, and this uncertainty led to the abandonment of the process.

The theory of welding steel to iron is excellent, and the practice is very satisfactory when the conditions are properly provided for. We have seen absolutely perfect welds made in this way—welds in which no test could discover the slightest want of continuity of the mass. But the present practical difficulties must be overcome. The plan shown in the "Engineer" is not trustworthy; nor is it new. Dr. Percy describes the same thing as proposed for the manufacture of tyres. And we have heard that it was proposed in this country at a much earlier date than our use of it. Here is a fine field for experiment, and we hope that this grand principle will be successfully worked out.

PULLEYS FOR SHORT BELTS.—Messrs. Gwynne, centrifugal pump makers, of London, use the arrangement shown in the cut, for saving space and strain in the use



of short belts. The driven pulley C is placed close to the driver A, so that the belt touches but a small portion of its circumference. The belt, therefore, has to be very tight; and to relieve the journals from the great pressure and wear thus imposed, the pulley B is placed intermediate between the others. This intermediate pulley is recessed in the center of its face, so as to bear on the others at the edges only. The arrangement is said to work well, and is more fully illustrated in "Engineering" of January 22.

LARGE HYDRAULIC TESTING MACHINE. —Messrs. Paulding, Kemble & Co., West Point Foundry, are making for L. B. Boomer, Esq., the eminent bridge builder, a machine for testing full-sized parts of bridges—rods, castings, etc.—up to 40 feet length and 400 tons pressure, either thrust or pull. The cylinder is 17½ in. diameter, and nine inches thick; the stroke eight in. The ram is single acting, being brought back by a rack and pinion. The cylinder is hung on trunnions—in fact it would be taken by an artilleryman for a 17½ in. mortar. When pointed in the direction of the 40 ft. bed-plate, it pushes directly upon or compresses the piece to be tested. To bring a tensile pull on the piece, the cylinder is turned away from it, and the power is brought to bear on it by means of a cross head, cross tail, or head block, and two side rods. The side rods are forged from Bessemer steel, and are four inches square. The cost of the machine will be about $5,000. Such a machine, for testing full-sized parts, has long been wanted in this country. The tests of little, short specimens, turned down to a mere wire in the middle, are not accurate, and the changes of figure are not easily measured.

STEAM CULTIVATION.—The success of steam cultivation was long ago established, and to say that steam is cheaper and better than horses in the field is as trite as to say the same of it on the railway. It is no longer a question of steam *v.* horses, but of the newest *v.* the earlier forms of steam tackle. More powerful engines, of much better construction, and worked at higher speeds are now in use, and some of them, working up to 100 indicated horse power, are hauling six and even eight-furrow ploughs in moderately stiff land, or dragging cultivators from 12 ft. to 15 ft. wide, and that at a rate of four miles an hour. The money saving had been proved by many cost sheets, and as for the work itself, it could be done in all weathers, done upon land which horses could not touch, or where they could not stand, done at a faster pace, the pulverization of the soil being as the square of the speed at which it is knocked to pieces; and then there was not a single one of the hoof-tracks, where horses' feet, like pavior's mauls, ram the ploughed earth into a hard pan like a pavement—hoof tracks, of which, with a full team in heavy ploughing, there may be as many as 300,000 to the acre.

THE SUEZ CANAL.

AUTHENTIC ACCOUNT OF THE WORKS, MAINTENANCE, DIFFICULTIES, WORKING, ETC.

Compiled from a letter by Mr. John Fowler to the London "Times."

Port Saïd Harbor.—A harbor for the entrance to the canal has been constructed at Port Saïd by running out into the sea two breakwaters formed by artificial blocks of stone. These are composed of one part of hydraulic lime from France, and two parts of sand obtained on the spot, and are therefore really hard mortar. The harbor is intended to answer the double object of protecting vessels from heavy seas and of arresting the alluvium brought down by the river Nile, so as to prevent its choking up the channel. The western breakwater extends from the shore 2,400 yards in a straight line towards the north, and then with a slight angle towards the east extends 330 yards further. The eastern breakwater leaves the shore at the distance of 1,530 yards of the commencement of the western breakwater, and extends nearly north for a distance of 2,070 yards, at which point it is 760 yards from the western breakwater, and this distance constitutes the width of the entrance. The portion of the harbor affording shelter to vessels is nearly 500 acres in extent, and, although the depth of water is not sufficient for the largest men-of-war, it is quite sufficient for ordinary merchantmen, if the present depth be maintained.

Large quantities of alluvium are constantly brought along the shore from the Nile, and since the construction of the western breakwater this deposit has changed the line of the shore, while large quantities have found their way through the interstices of the artificial blocks of which the breakwater is composed, into the harbor, and are forming deposits there; it will be found necessary to make this breakwater solid. It is possible this outside accretion may require at some future time a prolongation of the breakwater, and it may be that northerly winds will occasionally bring sand into the harbor; but I do not consider such contingencies to constitute any real objection to the design, or likely to be formidable in expenditure, considering the gigantic character and objects of the whole undertaking.

Divisions and Sections of the Canal.—The canal may be conveniently divided into the following portions:

	Miles.
1. Port Saïd through Lakes Menzelah and Balla to near El Ferdam	37
2. From near El Ferdam through the great excavation of Seuil d'el Guise to Lake Timsah	9½
3. Through Lake Timsah	5½
4. From Lake Timsah through the excavation of Seuil du Sérapéum to the Bitter Lakes	7½
5. Through the Bitter Lakes	23½
6. Through the deep portion of Chalouf Cutting	5
7. Thence to Suez and the end of the canal.	11
Total	99

With minute exceptions the whole of the canal is now being excavated and completed according to one or other of the following sections:

1st. 196 ft. in width at the surface of the water, and 26 ft. deep for 72 ft. at the bottom. The slopes are two horizontal to one vertical, with one or more horizontal benches of 10 ft. in width, according to the depth of the cutting.

2d. 327 ft. in width at the surface of the water, and a similar depth of 26 ft. for a similar width of 72 ft. at the bottom. The lower part of the excavation is also two horizontal to one vertical, but the slopes above and below the surface of the water are five to one, and a horizontal bench of 58 ft. connects the two slopes.

It will be observed in the description of the second section that the slope at the surface of the water is flat (five to one), and provision is now being made for protecting this slope with rough stone pitching, trimming the upper slopes, and otherwise treating it as a finished work. This may be safely done, because the section is so arranged that the canal may be widened at any subsequent period without disturbing any of the work already done. With the first section, however, the case is different. This section has been adopted in the deep cuttings to effect the largest saving possible in the quantity of excavation, and, therefore, if a future widening of the canal is required, one or both side slopes must be thrown back, and a considerable portion of the present work interfered with. As a rule, no stone pitching or other protection against the wash of passing vessels, or wind, or current, has been provided for the part of the canal where this section has been adopted, although the slope at the surface of the water is two to one.

At each end of the Bitter Lakes careful provision is now being made by temporary weirs and sluices at the sides of the canal for the admission of water into the lakes from the Mediterranean and Red Seas. This provision has been calculated with reference to the time and quantity of water, and a sufficient margin appears to have been given for possible contingencies.

THE WORKS AT SUEZ.—These consist chiefly of an entrance channel into the Red Sea, increasing gradually from 72 ft. in width at the bottom to 980 ft. of a basin or dock, and a considerable extent of reclaimed land.

WORK DONE AND TO BE DONE.—The total quantity of work in cubic meters of excavation originally required for constructing the canal according to its present dimensions and design was as follows:

	Cubic meters.
Total work	78,000,000
Work executed up to Dec. 15, 1868	53,000,000
Leaving still to be executed	25,000,000

The number of men, animals and materials which were on the ground and available for the work on the 15th of December, 1868, was as follows:

Workmen	8,213
Camels	368
Donkeys	116
Dredging machines	60
Inclined planes of railways	22

The quantity of work yet remaining is very large, but taking the progress made during the last few months, and applying the same rate for the future, it appears to be possible that in the absence of some unforeseen contingency the canal may be sufficiently completed for the purposes of traffic during the present year.

MAINTENANCE OF THE CANAL.—The question of maintaining the canal and its harbor of Port Saïd permanently open for traffic has excited almost as much professional and public attention as the construction itself, and in some minds probably much greater doubt and difficulty have been felt on this than on any other point.

The difficulties of maintenance may be divided as follows:

1. *The Prevention of Nile deposit from choking up Port Saïd.*

The remedy for the mischief, which may be said to have commenced and to be now continuing (and to which we have referred above), is either to admit the sand to pass through the breakwater and then depend upon dredging, or to make the breakwater solid, and encounter the difficulty, whatever it may be, of its greater accumulation outside. The rate of accumulation in the angle formed by the western breakwater was naturally very rapid in the commencement, because the area was small, and the water was impounded in such a position as to be almost without motion; but as the new shore formed by the deposit advances seaward this rate of advance is rapidly and constantly decreasing. The time has not been sufficient to collect adequate observations by which any law or formula could be founded to represent the future rate of the advance, but it is, however, very clear that many years must elapse before the line of shore can possibly reach down to the angle of the breakwater, and it may be that at or near this point the accretion seaward will cease altogether; but the greater probability is that, although it may have become small, it is still going on, and the necessity of extending the western breakwater, at some future time, further into the sea, is likely to be required. No apprehension need be entertained as to the channel and harbor being silted up and destroyed, but at the same time considerable expense in dredging will be constantly required.

2. *The Impossibility of Preventing the Sand of the Desert Blowing into the Canal in Quantities totally Unmanageable.*

This objection has been felt to be one of great weight, and when it was considered generally and without the correction of local knowledge it appeared to be fatal, because if the whole or nearly the whole distance from sea to sea had been through a desert composed of fine drifting sand it would have been hopeless to maintain the canal open; but, fortunately, the only portions of the canal which will be liable to be affected by the sand of the desert to any extent worthy of consideration are the two excavations on each side of Lake Timsah—viz: Seuil de Guise on the north, and Seuil du Sérapéum on the south. Fortunately, a tolerably satisfactory means of ascertaining the annual amount of drifting sand has been afforded by an investigation lately made during a period of twelve months, and the result is that 40,000 cubic yards was found to have passed into Seuil de Guise, and 270,000 cubic yards into Seuil du Sérapéum. These quantities, no doubt, are very large, and it is quite possible that during some years they might be exceeded, but the company are making provision to diminish the quantity by trying experiments with trees and shrubs, so as to plant the slopes and the ground for some distance on each side of the canal. It is also probable that water from the fresh-water canal will be made available for forming an extended oasis at and around this portion of the canal. These operations will be somewhat expensive, although they are doubtless prudent and desirable, but after every precaution has been taken it will be necessary to keep one or two powerful dredges in Lake Timsah to keep the canal clear from drifting sand.

3. *The Difficulty of Protecting the Banks against the Destructive action of the Wave caused by passing Vessels.*

It will be found necessary to make a proper and immediate protection of the slopes by stone pitching above and below the surface of the water along the whole course of the canal if the traffic is to be conducted at a reasonable rate of speed; the engineers of the Canal Company have arrived at the same opinion. This work will no doubt be executed much more conveniently and economically after the canal is opened throughout, and the large quantity of stone required can be conveyed without charge; but, on the other hand, it will be more difficult to place the stones below the level of the water, and probably the slopes may have sustained some mischief before the work can be done.

4. *The Impossibility or Difficulty of Supplying the Abstraction of the waters of the Bitter Lakes during the Evaporation of the Summer Months through the Ordinary Section of the Canal between the Bitter Lakes and Suez.*

The vast extent of the Bitter Lakes (100,000 acres in superficial area) when connected with the tidal Red Sea by the Chalouf excavation, will produce in the summer months, when the evaporation is greatest, peculiar currents and hydraulic phenomena. The largest daily evaporation or abstraction will amount to about 250,000,000 cubic feet of water, and this will be chiefly supplied from the Red Sea, which is far nearer than the Mediterranean, and has a tidal range of about 6 ft. in spring tides, and 2 ft. at neap tides, while the Mediterranean has a far less tidal range. The currents which will thus be created by evaporation and tide will be sufficient to assist or retard navigation, as they will probably approach, if not exceed, two miles per hour, but they will scarcely be strong enough to affect injuriously the bottom or sides of the channel through the Chalouf cutting after the proper protection by stone pitching has been carried out.

It is possible that a strong south wind may somewhat increase the velocity of this current by slightly raising the ordinary tide at Suez, and that lateral absorption, evaporation, and waste round the shores of the Bitter Lakes into, and through, the sand of the desert may increase the amount of the water to be daily supplied; but these disturbing causes will not probably be sufficient to make any appreciable difference in the velocity. It would, however, have been desirable, in my opinion, that the canal should have been originally constructed on enlarged dimensions between the Bitter Lakes and the Red Sea, if the resources of the company had permitted.

Traction Power to be Employed on the Canal.—A special committee, or commission, has been engaged for some time in investigating this question, and has considered many expedients and suggestions. At one time it thought that a continuous chain along the bottom of the canal, similar to that used for the ferry at Portsmouth, would be applicable, but it is now understood that steam vessels (except those with paddle-wheels) may use their own power, and that any vessel may be towed through the canal by steam tugs, the speed to be limited in all cases, as may be settled hereafter. This is doubtless the best decision, both for economy and convenience.

Several important questions suggest themselves in the working of the canal, such as the impossibility of two large vessels passing each other until the canal is enlarged; but this difficulty must be dealt with by regulations very similar to those adopted on a single line of railway. If, however, the traffic should rapidly become very large, it is possible that several passing places will have to be provided without waiting for the widening of the whole canal.

A strong side wind would also be a considerable difficulty, and occasionally it may be found to be almost impossible to keep a large vessel from the sides of the canal. In the Caledonian canal it is well known that this difficulty is frequently experienced even with small vessels, but in Egypt very strong winds from the east and west are not common, and the difficulty will probably not amount to more than a simple retardation of the speed of the vessel, and the necessity of lowering all masts and rigging capable of being lowered, but one or two attendant tug vessels, when required, can be made available for the purpose of enabling a vessel to keep the channel of the canal. Doubtless many unexpected matters, both of difficulty and convenience, will develop themselves in the working of the traffic, but these will be best dealt with as they arise.

PROBABILITY OF THE USE OF THE CANAL.—The Suez Canal is so peculiar in itself and in the manner in which localities are affected by it, with respect to their maritime distances from each other, that it is almost impossible to foresee the manner and degree in which it will attract traffic to itself. It may, however, be assumed with tolerable safety that, provided the canal be maintained in full depth and efficiency, and the charges made for its use are not unreasonable, the steam passenger and mail traffic now carried on between Europe and India will chiefly pass through the canal. It may with equal safety be assumed that sailing vessels, which would not only require steam tugs through the canal, but also down the Red Sea, will not use the canal. A certain amount of local traffic between the Mediterranean and Red Sea ports will no doubt use the canal.

The great element of uncertainty, and one on which the commercial success of the Suez Canal will chiefly depend, is whether new sailing vessels, with adequate auxiliary steam power, specially adapted to the canal and the Red Sea, will be constructed, so as to divert the large traffic now being carried around the Cape. I think enterprising firms will try this experiment, and if successful, the Suez Canal will secure a great position both for usefulness and profit.

ENGINEERING IN SPAIN.

FOREIGN CAPITAL AND TALENT—BAD RAILWAY MANAGEMENT.

From "The Engineer."

No country owes so much to foreign labor, foreign science, and foreign capital as Spain. Indeed, it is wonderful that English, French, Belgians, and Hebrews, should have done as they have done for a country where the peculiar nature of the soil and the eccentric character of the inhabitants must have presented difficulties at every step. The credit of having introduced the railway system into Spain is divided between an English engineer, Mr. Vignoles, a Jewish banker, Mr. T. Péreire, and the late M. Perdonnet. The latter, by the way, made a serious mistake, when he said, "Railways will change the aspect of that country." They have no more altered the customs of the Spaniards than the recent revolution has altered the state of the "*Caminos de Hierro.*" As to the construction of railways, and their subsequent repairs and management, the Spaniards have had very little to do with them. The lines were surveyed by foreigners for a good reason, namely, that very few Spaniards are sufficiently acquainted with the exact sciences to make a correct plan or to level a trial line.* The rails, turntables, switches, &c., were supplied by English or Belgian ironworks. The rolling stock was supplied partly by English, partly by Belgian and French builders. Several Belgian firms are said to have supplied rolling and permanent stock to Spanish railway companies on condition of taking part payment in shares or bonds, a transaction which has proved ruinous to them, notwithstanding the government guarantee.

The working of railways has been left as much as possible, for obvious reasons, in the hands of the native functionaries. Gentlemen of this class are as numerous and as zealous in Spain as they are now in France, or as they were twenty years ago in Austria. Railways under official management are easily recognized. Mail trains arriving at Madrid five or six hours behind time ;† express trains carrying cattle and metals, as we have ourselves seen on the "Norte"; passengers turned out of their trains at night, and obliged to wait two or three hours in the open air, without refreshment or shelter; trains starting before the advertised time of departure. Such is Spanish management. And these irregularities are so frequent that they have become regular, punctuality being the exception. Native passengers do not complain as often as might be expected, because they are, as yet, not sufficiently acquainted with railways to know what they should be, and what services they might render under proper management. Wherever a large foreign staff is employed—as on the Ciudad-Real and Badajoz line—punctuality and even comfort may be expected.—The labor supplied to Spanish railway com-

* This is certainly not true of the same race in Cuba. The study of engineering is very largely and thoroughly pursued by Cubans, in our scientific schools, especially in the oldest if not the best of our engineering schools—the Rensselaer Polytechnic Institute.—*Ed. V. N.'s Mag.*

† This frequently occurs on the southern lines.

panies is divided between English platelayers, French fitters, Piedmontese underground excavators, Belgian openwork excavators, and Spaniards, who excel in no particular trade.

Spain possesses a very rugged and barren soil, but the mines of the Peninsula are very rich; and some of the richest are, by a sort of natural compensation, in the most barren districts. Coal, iron, copper, and lead ores are very abundant. Santander exports large quantities of "red ore" to the Welsh iron districts. The colliery (Cuenca) of Belmez, situate in the Sierra Morena, between Castuera and Cordova, appears likely to prove very rich. We believe that all the coal consumed by the "traction" of the Ciudad-Real and Badajoz line is supplied from this mine, though it has not been worked long. The Cuenca of Belmez was surveyed by French engineers some years ago. It is now conceded, together with the Badajoz line, to a French company (Fines-Lille.) The oldest mine in Spain in probably that of Almaden (mercury); that is worked, we believe, by Spaniards. Almost all the others are surveyed and managed by foreign companies, foreign engineers, and foreign work men. The mines of Thelva, Tarsis, Rio Tinto (copper), and Alcañees (tin), were surveyed and claimed by a French engineer—M. Ernest Deligny—and put into working order by a French capitalist—the Duc de Caze. Huelva is now in the hands of an English company.

The harbors of Spain have not given much employment to foreigners. The big moles of Tarragona, Barcelona, and Cadiz, were made entirely, we believe, without foreign assistance, and paid for by the State. But the canals have required foreign engineering talent and foreign capital. Thus Spain is indebted to foreign nations for her mines, railways and canals. She is also deeply indebted to them for money, the Spanish government having frequently issued loans, which have been subscribed in a great measure by English capitalists. Three countries especially—England, France and Belgium—have assisted Spain in such a manner as to give substantial proofs of their goodwill towards the Spanish nation, and of their confidence in the traditional honor of the Spaniards. Unfortunately the late government have destroyed that confidence and repudiated their engagements with such coolness as to induce a suspicion that they never intended to fulfil them. We may reasonably hope that the present government has better intentions and a more honorable character; but it will be a hard task for the provisional or any other administration to restore the national credit.

Converting Cocoa-nut Husks into Fibre.—The "Mechanics' Magazine" thus describes the process: The shell or outer covering of the nut is first soaked in a tank of water kept warm by steam. When sufficiently soaked, the shells are conveyed to a hopper, through which they are fed to a crushing mill, which consists of two coarsely-fluted rollers, between which the shells pass and are crushed. They are removed thence to the fibre mills. Here the shells are drawn in between two rollers, behind which are arrangements for tearing away the finer fibre and leaving the coarser in the hands of the operator, who presents first one and then the other half of the shell to the action of the mill. The coarse fibre is then carried away and prepared for conversion into brushes and brooms. The finer portions of the fibre are removed from the mill, and undergo a process of final dressing. This is effected by feeding them through a hopper into a circular screen, in which an Archimedean screw rapidly revolves. The fine fibre is delivered at the mouth of the screen, whilst the dust and smaller particles of fibre are carried through the sieve. The fibre thus produced is used for making mats and matting; the siftings find a ready sale with florists and market gardeners for manure. The sweepings and refuse are collected and burned under the boilers.

Engineers and Architects.—The kind of tacit estrangement which now exists between architecture and engineering, imperils public interests, and results in the abuse of popular taste. The engineer can no more afford to work without the architect on his great works than the architect in similar case can dispense with the engineer. In the one case we are threatened with mere size and solidity, without sightliness; and in the other, with works which promise an antiquarian rather than a true artistic interest as productions of our own day; while the art of the architect threatens to fail in its highest aim—the elevation of public taste and the excitement of popular sympathy—because it refuses to bend to the wants and discoveries of the time.

It is in no sense derogatory to the prestige and honor of either profession that the public should long to see the divorce between them annulled. Each has its special excellence and its special province; we only desire to insist that the intellect of both is essential to great and lasting successes in our public structures of every class. Life is far too short in our day, the competitive principle too active, and the exigeant demand for speedy execution of our work too pressing, to allow of any one man achieving high excellence in the character of architect and engineer at once, as we now understand the high functions of the two professions. Your modern engineer can as little be expected to design a town hall or a cathedral up to any noble mark, as your architect can be asked to construct a suspension bridge or a railway station on a grand scale. There may be, and have been, here and there, eminent instances of men gifted with the rare combination of engineering and architectural talent; but they are so scarce and so far between as not to affect our argument. How many architects, for example, are there among us to-day, who could, *de novo*, and without existing models, at once design *and* construct a Westminster Abbey or a St. Paul's Cathedral? Similarly, it may be asked, where is the engineer who could construct *and* design them? The architect may be able to design, and the engineer to construct works of such a mark, but it is idle ever again to expect that either can do both unaided by the other.—*The Architect.*

PERMANENT WAY OF THE PENNSYLVANIA RAILROAD.—It is highly gratifying on many grounds—comfort, security and engineering fitness—to strike the new permanent way of the Pennsylvania railroad, after rattling over the tracks of various roads farther east. The smoothness, the apparent absence of joints, the sailing motion, in comparison with the hard gallop of wheels over unfastened rail ends, is even better than English railway riding, because of the lateral and vertical articulation of American cars. The steel rails of this line, now in use and coming into use as fast as the Pennsylvania Steel Works can turn them out, are four and one-half inches high, four inches wide on the flange, and weigh 67 lbs. per yard. This height gives room for a thoroughly good fish-joint. The sleepers are two and one-half feet apart centers, laid on good ballast—generally blast-furnace cinder.

RIVER FLOODS.

LACK OF PREVENTION—DESTRUCTIVE EFFECTS ON PROPERTY, HEALTH, SEWAGE AND DRAINAGE.

In this country, perhaps less than in England, annual sufferers by flood take marvelously little pains to keep their property and dwellings out of reach of inundations, and still less to change the beds of streams and the defences of banks to avoid their destructive effects. The following considerations on the subject are from "The Engineer:" Once a year at least, and frequently oftener, inundated lands and submerged fields testify to the total absence of restraint imposed upon our rivers and streams, and the fury with which they exercise their uncontrolled depredations. Bearing in mind the patient passiveness and apathy that mark the conduct of the owners and occupiers under these annual inflictions, one might almost be inclined to believe that, instead of ruin and devastation constituting their invariable attendants, they were accompanied with the same advantages that follow the periodical inundations of the fertilizing Nile. Not only are the overflowing waters permitted to extend their ravages over outlaying districts and the open country, but there are very few towns where any provision is made to check the progress of floods and arrest the violence of the torrent. It is only the other day that Manchester finally decided, when driven to extremities, that something must be done in the matter, and has undertaken the construction of the necessary works, under the advice and superintendence of one of our most eminent hydraulic engineers.—If—in the case of towns—precautionary measures are adopted only after so much hesitation, procrastination and uncertainty, it is difficult to predict the period at which, the evils resulting from floods in the open country will undergo any permanent abatement. The embankment of a river for that portion of its course running through a town improves the river itself, and a handsome wall adds to the appearance of a city. But beyond this no good is effected. Above and below the wall-bound stream the waters remain in their state of original liberty, ever ready, upon the first addition they may receive to their turbid contents, to break out into open rebellion. It is even questionable whether the penning up, as is were, of the contents of the swollen channel, does not increase the violence of those portions of the stream unconfined by the granite boundaries. That the improvement—whether it consists of widening, narrowing, strengthening, or deepening the river—is confined altogether to the small portion affected, there can be no doubt. It is apparently incredible that we, who, in the nineteenth century, have rendered all the powers of nature obedient to our will and subservient to our interests —we who have made the opposite elements of fire and water administer to our comforts and contribute to our welfare—should permit our rivers and streams to range at large unchecked and unrestrained, and annually to commit ravages costing thousands to repair.

It is not our province to inquire into the reasons why houses come to exist in such close contiguity to rivers notorious for inundations, or why people elect to reside in abodes, which are reared upon so fearful a source of sickness and death as damp foundations. It has been lately advocated by a well-known authority, that every dwelling house should stand upon its own area of concrete or other waterproof substratum. The mere insertion of a course of slates, a layer of asphalt, or a coat of cement above the footing course, is not sufficient to endow a house with immunity from those evils which directly result from too close a communication with a damp soil. Unquestionably the true principle is that which would require the whole of the area, upon which the building is raised, to be overlaid with a waterproof layer; and we trust that we shall ultimately witness the enforcement of this proviso, by the authorities charged with the supervision of the erection of new buildings.

There is another light in which to view the evil results springing from the wholesale inundation of arable and fertile land, which materially affects the great question of sewage irrigation. It is often urged that it would be impossible to apply sewage to lands that are particularly well situated with regard to levels, and in other respects admirably adapted for its reception, owing to the great quantity of water existing in and about them. The agriculturist exclaims, "We have more water than we know what to do with, and you want to send us a still larger supply!" This brings us to a consideration of another feature in connection with the utilization of sewage, which is not regarded with the attention it deserves. It is the question of drainage. Lands subject to periodical floodings must necessarily present greater obstacles to the carrying out an efficient system of drainage, than others more favorably located. One of the first steps taken at Barking was thoroughly to drain the subsoil; and, in fact, this operation was carried out to a greater extent than was absolutely required, as experience subsequently demonstrated. In an instance of the nature alluded to, it will, nevertheless, be admitted that it was better to err upon the safe side. A work of supererogation was infinitely preferable to the fault of omission. If a farmer will not go to the expense of draining his land and putting it in proper order to benefit by the application of sewage, he cannot in common fairness, allege that the non-utilization of that fertilizing medium is due to a self-inherent defect. Moreover, supposing that all the lands subject to inundation were properly drained, yet the overflowing of the natural water-courses would, for a time at least, effectually prevent the application of sewage. From the statements already made, it is manifest that by the annual outbreaks of our rivers and streams, many thousands of acres are either permanently or temporarily prohibited from benefiting by the application of sewage. What constitutes a further aggravation of the evil is that these very lands—from their physical features and natural position—are calculated to receive the sewage by the readiest and cheapest method possible, namely, that of gravitation. We could point out instances where land situated along the banks of the Medway, and, in every sense well adapted for the utilization of sewage, cannot be so employed in consequence of the floods to which it is constantly subjected

It would scarcely be reasonable to urge that all rivers should be prevented from trespassing beyond the limits of their natural channels, by the erection of heavy walls similar to those constituting part of the Thames embankment. At the same time, there is not the slightest doubt but that in numerous instances, especially in those localities where labor and materials could be procured comparatively cheaply, it would pay, in the long run, to construct a sound strong wall, instead of the stereotyped bank with its central core of puddle and inner and outer slopes. Only those who have had the care of these banks are acquainted with the watching they require, amounting at times to a regular patrolling. They are a continual source of anxiety and annoyance to the proprietors of the lands protected by their ambiguous influence, and a never-ending cause of expenditure.

There is no question but that the tortuous course of some rivers, the multiplicity of twists and abrupt bends, mainly contribute to the occurrence of floods. It is in the "elbows" that the marshes and swamps principally exist. If we imagine a rapid torrent coming down a straight reach, and on a sudden encountering an abrupt bend, nearly at right angles with its previous course, the volume of water cannot adapt itself to the sharp sinuosity, but overleaps the bank, floods the land situated in the concave part of the "elbow," and whatever is left of it falls into the channel beyond the bend.—Were more attention paid to improving the course of our rivers and the cross section of their channels, the work of the banks would be considerably lightened. As it is, they have not merely their legitimate duty to perform as confining or retaining walls, but in the majority of instances they have to withstand a pressure and violence which ought never to be brought upon them, which is due to the crooked character of the river's course. Floods are due, not so much to the gradual rising and swelling of the waters so as to uniformly overflow the banks, as to the fact that they accumulate with a rapidity exceeding that with which they are able to get away. Owing to the impediments in their course they become piled up, as it were, at certain points, to a height far exceeding that of their confining banks, while at others their level is scarcely perceptibly altered. If a little more money were spent in widening, straightening, and deepening the defective portions of our rivers and streams, we should hear less of banks being breached, meadows flooded, and towns inundated.

COAST DEFENCES.

From a lecture by Col. Jervois, before the Royal Institution.

Coast defences in Anglo-Saxon times consisted, in the main, of predatory incursions and plundering expeditions. The progress of civilization has introduced better usages into the practice of modern war; but if it had not, the length of our coasts is far too great, and the accessible points far too numerous, to render it possible to fortify them all. When we speak, therefore, in the present day, of our coast defences, we must not be understood to advocate a vain attempt to secure by defensive works every vulnerable point, but to provide for the protection of our national dockyards and arsenals, and of our main commercial ports.

For the general defence of a vast empire we must first of all, and mainly, depend upon our fleet. It is to the fleet we must look for our first line of defence against invasion, to maintain our communications with our foreign possessions, and to protect our commerce at home and abroad. But the bases on which our naval power must rest are the ports, dockyards, and arsenals, in which our fleets and squadrons are harbored, coaled, and refitted. Thus we have naval establishments at Portsmouth, Plymouth, Chatham and Pembroke, at home; at Bermuda, Malta, Gibraltar, and other places abroad.

These places are the roots from which our naval power springs, and they require special protection against attacks that may be made upon them during the absence of the fleet, either by hostile naval forces alone, or by combined naval and military expeditions. Even if it were possible that a fleet sufficient to fulfill all these duties could be maintained, such an application of the resources of the nation would lead to an expenditure of public money, far exceeding that which would suffice for the defence of the country with the aid of other means. Further, if the several sections of our navy were employed for the protection of the arsenals whence they are maintained, we should be using the fleet to maintain the dockyards, instead of the dockyards to maintain the fleet.

The means by which these places should be defended are by big guns above water; big mines below water, placed at proper distances in advance of the object to be defended. It used to be the fashion amongst professional men in this country to consider this latter mode of defence as being incapable of practical application, but of late years a very different opinion has prevailed; and through the efforts of Lord De Grey's committee we are now in a position to apply this system of defence to any extent that may be required for the protection of our harbors and other points upon our coasts. The question then arises, how far, if at all, does the use of the submarine mines affect the employment of forts and batteries for defence against naval attack. Forts and batteries are still required in all important cases to cover the torpedoes, and prevent their being tampered with. It must also be remembered that whilst the submarine mine is harmless unless the ship comes near it, the shot from the battery can injure the ship, whatever may be her position, within effective range. Further, although probably our harbors might be efficiently obstructed by torpedoes at from seven to fourteen days' notice, yet one condition is that the weather should be sufficiently favorable to allow them to be exactly laid. There are, again, certain positions where, even if the torpedoes were laid, they might be disturbed by a violent storm, and possibly an attack on the positions in which they were to serve might take place before they could be renewed; and although the periods of the year at which these difficulties might arise are short, yet the bare possibility of interference in the application of a complete torpedo system prevents our placing entire reliance on such a defence for the protection of places on which the warlike power of the nation, both for offence and defence, must in a great measure depend. Therefore, although submarine mines are a most important element in the defence of our harbors and coasts, and add greatly to the power of our forts to resist a naval attack, they must not be regarded as substitutes for permanent works of defence at our naval arsenals and harbors, and of our important forts.

To proceed now to consider the employment of big guns above water. These, with all the numerous accessories for their service, must be placed in positions so protected and arranged as to give them a decided superiority over the artillery of assailing ships. The question then arises, whether they shall be placed afloat in strongly protected vessels—*i. e.*, in floating batteries—or at fixed points either on land or on shoals—*i. e.*, in forts. It is often said, "Why don't you protect your ports by floating batteries alone?" The same reasons, however, as have been before adduced against the employment of our sea-going navy, prevent our employing special floating batteries for this object. It would necessitate our maintaining, at each of our chief ports, a naval squadron sufficiently powerful to resist the attack of superior forces of the enemy.

In the construction of coast batteries two main points have to be attended to: 1. To give cover to the guns and gunners. 2. To develop, as far as possible, the lateral range and rapidity of fire of the guns. These two principles being somewhat antagonistic, has so far always been one of those difficulties to be reconciled, and it is to the fluctuation in the relative importance of cover or fire, of protection for offensive power, that different designs for coast batteries are due. The simplest form of battery is a mass of material in front of the guns, and either of earth, masonry, or concrete, according to the circumstances of the site. It is evident that the greatest extent of range may be obtained from the guns if they are so mounted as to fire over this parapet—or, as it is called, *en barbette*—for their field of view is entirely unobstructed, and this simple system is well adapted for sites at considerable elevation, say 100 feet above the water, where neither the guns nor gunners would be much exposed to the fire of a hostile vessel. When, however, the site is low, the enemy's view of the guns in a barbette battery would be such that he would easily silence the battery; and it has therefore been necessary in such situations to mount the guns so that they may be fired through openings or embrasures cut in the parapets, instead of firing them over the parapet. The Moncrieff gun-carriage has solved many of these difficulties; but armored and covered defences are, nevertheless, essential under many circumstances, so that the fort might be protected properly from every species of attack.

The question of the defence of our great naval arsenals, in the event of an enemy obtaining a footing on our shores, was next discussed. It would, to say the least, be very unwise if we were to conclude that invasion is impossible because it is difficult. The best disciplined and the greater part of our military forces must obviously be employed to cover the capital; we must, therefore, arrange our plan of defence so that as few disciplined troops as possible may be necessary for the defence of other points in the country which must be defended, but which cannot be covered by the operations of the main army. A mistake is commonly made that because the arsenals and yards referred to are extensively fortified, the garrisons of those places must be largely increased. The case is precisely the reverse. Supposing all the outer line of forts to landward, at either Portsmouth or Plymouth, to be fully manned at the same time, (which would be quite unnecessary, not more than one-half need be fully manned at the same time.) only between 6,000 and 7,000 men would be required for the purpose at each place respectively, and only a very small portion of these need be regular troops. The remainder of the garrisons would consist of a movable force, which in any case we must have for the defence of these places, but which, in the absence of the forts, must be of sufficient strength and sufficiently disciplined to meet the enemy in the open field, whilst with the forts it may be comparatively small in number, and only disciplined to take up a fighting position, under the support of the works at that part of the fortified line assailed. Unfortified, an enemy would only have to detach from the main invading army about 15,000 or 20,000 men to effect, in a few days, the destruction of all our ships and naval establishments at Portsmouth. Fortified, he must employ an army of at least three times that number, and must have a considerable time at his disposal to undertake a regular siege. Unfortified, no force that, in the case referred to, we could afford for the garrisons of these places could protect either against the attack of 15,000 regular troops. Fortified, there is no difficulty in providing the numbers and description of troops that would be capable of making a good defence of these nurseries of the navy. Unfortified, they at once fall if an enemy were to obtain a decisive victory over the army in the field. Fortified, they remain in our hands even under such untoward circumstances, and thus enable us to avert the destruction of our naval power at a period when all the resources of the country will be required to enable us to retrieve the position we had temporarily lost.

We are often told that these works are unproductive, and so, in one sense, they are; but who shall say what effect permanent measures of defence may have upon the position of a nation. But we are met with other objections. It is commonly said that there is no use in constructing permanent fortifications, because the inventions of one age render useless the efforts of the previous generation. History, however, does not support this statement. At this moment we are turning to account, and with good effect, works erected by Henry VIII, more than three centuries ago. In like manner the works constructed in the time of Charles II, and in the reigns of George II and George III, all more or less form parts of the system of fortifications we are adopting at the present day. Then we are told that the measures are so extravagant. The fact, however is, that by the aid of fortifications we are enabled to defend the empire with fewer troops and a smaller navy than would otherwise be necessary, and that they thus tend greatly to economy. If we are to make provision for defence at all, it is only by the aid of fortifications that we can have an economical system of defence. They say, then, that our fortifications "lock up" troops. It has been shown, on the contrary, they enable us to utilize our auxiliary forces, and to set the regular army free. Again, we are told that we ought to depend upon our navy; but the main purpose of the fortifications is to enable the navy to do its duty effectively. The navy is, without doubt, the arm on which we must mainly depend; but that is no reason why we should tie it down to our side. Lastly, they say "an enemy will not go near these fortifications." The reply is, that that is the very object for which they are provided. To sum up, the truth is, that to provide an efficient system of defence at the least cost to the state, the soldier, the sailor, and the military engineer, must each occupy his proper place. The navy and the army are the vital principle of defence, and fortified arsenals and harbors are the centers of refuge and action for both. Take away fortifications, and you are unable to turn your auxiliary forces to proper account; you leave an army utterly insufficient for the duties it has to perform—a navy scattered, unsupported, and with no protected home.

DURABILITY OF STEEL RAILS.

It is officially stated that out of the eleven thousand tons of steel rails in use on the Hudson River Railway—some of which have been down over three years—only eleven rails had broken up to January 1, 1869.—One broken rail to the thousand tons, is rather a different matter from a thousand broken rails a month, which was the breakage of iron rails on the Erie road last winter.

On the Erie road it is officially stated that only ten steel rails have broken out of the eight thousand tons in use. Some thousand tons of the above mentioned steel rails were made at Troy—the rest are of English manufacture. The success of steel rails on the Lehigh Valley road is mentioned in another article.

The following letters from the President of the Philadelphia, Wilmington and Baltimore Railway give a complete history of the trial and use of steel rails on that road:

P. W. & B. R. R. Co., President's Office,
Philadelphia, Dec. 16, 1868.

Edward Austin, Esq., Boston:

Dear Sir—Your letter of the 15th inst. is before me. This company commenced the use of steel rails made at the Atlas Works, Sheffield, England, by John Brown & Co., in August, 1864. At present we have laid and have in use upon the most trying portions of our line, about twenty-five miles of single track of same make. We have never broken one in use, nor taken up one on account of wear or defect. In the middle of a much used portion of track laid with steel in 1864, near Philadelphia station, we laid one rail of American iron, and have replaced it, as needed, by other rails of American iron, until we have used up sixteen iron rails, while the steel will wear for several years yet. My last information as to condition of track, shows that not one steel rail in twenty-five miles of track shows any imperfection or defect, but all are wearing truly and smoothly. No observant passenger will fail to detect the passage of a train from steel to iron, and vice versa. I cannot speak of makes other than Brown's, nor do we fail to inspect his *rigidly.* I have rejected 88 tons from an invoice of 600 tons. Mr. Joy's* failures may have been of other manufacture. They may not have been well inspected; they may have been punched or slotted, or any one of many other good reasons may be adduced for their failure.—But my experience is enough for me. On a road like this, where our iron does not last seven years on an average, true economy, as regards the rail expenditure alone, demands steel rails. The reasons which limit our purchase of steel to about 50 per cent of our renewals, are found in our poverty alone.

We were long since led by our experiments to the conviction that punching and slotting were very injurious to steel rails, and for two years we drilled them as the lesser injury. We now use a joint fastening which dispenses with all holes in the rails.† My last purchases of Atlas rails were at $100 gold, in Philadelphia, to be delivered in 1869, and of Welsh iron rails, guaranteed five years, at $83 currency in Philadelphia. I have also received 100 tons Barrow steel on trial, and have a contract for 500 tons Pennsylvania Steel Company's rails. We have also in use 500 tons steel headed rails made in Pennsylvania,* costing $113 currency, which promise well. I am offered steel rails of other makers at $92 gold in Philadelphia, but have completed our purchases of iron and steel rails for 1869.

The freedom from a defect in a track means also diminution of cost of repairs of locomotives and rolling stock, and enhanced safety of passengers. If we go on laying ten to fifteen miles per annum in steel, you will ere long see that our expenses for track repairs and in our shops, will be reduced considerably. While we are buying steel rails and charging their cost to "repairs," that account must be large. * * *

Very truly yours,
(Signed) ISAAC HINCKLEY.

P. W. & B. R. R. Co., President's Office,
Philadelphia, Dec. 22, 1868.

Edward Austin, Esq., Boston:

Dear Sir—I have yours of the 18th. The first steel rail imported has already worn out sixteen (16) iron rails, and we have not now any reason to suppose that the latter invoices are of inferior quality. But there is great fear on my part, that railroad companies will themselves tempt steelmakers to send a poor article, by buying the cheapest—first cost only considered—as they did with the ironmasters. It rests with railroad men to keep steel rails good by buying no poor ones.

We try steel with the chisel for *hardness*, with the trip-hammer for *toughness*, and for *strength* with the 2,240 lb. drop, fifteen feet, the rail resting on supports three feet apart. Rigid inspection only can save us. Having passed inspection, make no holes, or at all events, no *punched* holes in the rails.—Punching is bad enough for iron, but death to steel.

We, on Friday last, dropped our 2,240 lb. "tup" twenty (20) feet, upon a steel rail resting on supports three feet apart. The rail was merely bent. I have in my office a steel rail twisted, *cold*, into a regular spiral of one entire turn to two feet length, without crack or flaw.†

Very truly yours,
(Signed) ISAAC HINCKLEY.

* Waterman & Beaver's puddled steel heads.—*Ed. V. N.'s Mag.*
† We have twisted rails made by the Pennsylvania Steel Company, and by John A. Griswold & Co., as here stated.—*Ed. V. N.'s Magazine.*

HISTORY OF DECARBURIZING IRON.*

No. II.

HEATING THE IRON TO BE MELTED, BY THE WASTE HEAT OF THE MELTING FURNACE —CAST IRON FURNACE FLOORS—HEATING BOILERS BY THE WASTE HEAT OF FURNACES.

Gardiner, Robert. — 1788, June 5. No. 1,608.

Printed, 3d.

Manufacturing iron and other metals by a progressively multiplying air furnace. A series of compartments connected by flues from the multiplying furnace, and the flame and heat pass from one to the other. Each has a separate door, the further compartment being less hot than the more near; the first may be at a welding, the second at a red heat, and the third at a less heat, or if required, may be raised to a greater heat by adding another and separate fire communicating with the common flue. The waste of putting cold iron into the melting furnace is avoided, as it may be heated by the waste heat in the extra compartments ready for use.

Cast iron floors for the furnaces save the wear of the old sand floors.

Steam boilers may be heated by passing the waste flame and heat from the furnaces, round, under or through them.

Note.—*The patent does not* SPECIFY *using the waste heat of puddling furnaces, but it* COVERS *such use, in as far as a puddling furnace is and must be a melting furnace. Jones specifies using the waste heat of puddling furnaces in* 1822. (Sec p. 359.)

This patent is only four years after Cort's invention of puddling. It mentions iron furnace floors for the first time.

It is remarkable in specifying, 81 *years ago, the heating of boilers by waste heat—a thing which is claimed by several modern mill managers.*

OXIDE OF MANGANESE USED IN THE CONVERSION OF PIG INTO MALLEABLE IRON.

Reynolds, William.—1799. December 6. No. 2,363.

Printed, 3d.

"Preparing iron for the conversion thereof into steel." The invention consists in the employment of oxide of manganese, or manganese, in the conversion of pig iron into malleable iron or steel. No proportions or details are given.

Note.—*This is the first mention of manganese in the Patent Office records of the iron manufacture.*

THE SQUEEZER.

Hartop, John. — 1805. November 7. No. 2,888.

Printed, 3d.

"Method of preparing malleable iron, &c." The invention consists in the use of a kind of squeezer worked by a cam instead of a forge hammer or rollers.

Note.—*This is the first mention of the squeezer in the patent records.*

INTRODUCING AIR BLAST ABOVE THE GRATE.

Dimmack, Jeremiah.—1812. May 26. No. 3,569.

Printed, 3d.

"Manufacturing iron in its difficult stages or forms of blooms, slabs, piles, bars," &c., "or other malleable iron from pigs or plate iron in a puddling, balling, bloom, mill, sheet iron furnace, or any other air furnace," &c. "Take any furnace of the common construction," but the grates must not be large, and "less at one end than the other." "Level with and immediately above the top of the grate," introduce an iron blast pipe, with stopcock to regulate and shut off the blast, and put dampers in the chimney.

Note.—*Although referring, among other things, to the manufacture of malleable iron from pigs in a puddling furnace, this practice, as far as it supplies air above the fire, would not meet the modern idea of puddling, viz: decarburizing by means of the fettling, without the aid of air. (See Siemens on Puddling, Van Nostrand's Mag., Vol. I, No. 1, page 37.) Blowing in air above the fire in reverberatory heating furnaces is, however, practised in some of our best modern forges, especially for heating large masses. This patent at least hints at this practice.*

IRON ORE, SCALES, LIME, ETC., USED TO DECARBURIZE PIG IRON.

Mushet, David.—1815. July 27. No. 3,944.

Printed, 4d

The metallic contents of refuse, such as slag, scoria, cinder, scales, &c., are recovered and made available for producing "finers' iron or metal" in a furnace, called "a smelting finery," by "making use of the superfluous carbon" in pig iron, which is to be melted with the refuse in the following proportions: 300 or 400 lbs. of coke, 600 lbs. of pig iron (broken up), 180 to 240 lbs. of refuse and 150 lbs. of limestone, or by preference, 40 to 120 lbs. of burnt lime. When the charge is melted, the metal sinks to the bottom, and should be kept carefully covered with the melted scoria; no part is to be run off till the furnace is tapped. If, after the first or second tapping, the metal is not sufficiently decarburized, or "not high enough blown," the proportion of coke is reduced, or that of refuse increased.

* We omit several patents clearly and fully anticipated in previous specifications. The specifications referred to are printed and generally illustrated with plates. We append the price to each. They may generally be obtained from the Patent Office in London, through any American publisher. Editions are sometimes out of print for a few months, but new editions are issued from time to time. Those referred to in our former article are all printed. The price is 3d. each, except Onions', which is 7d. All the British specifications and engravings are on file and free to inspection at the Astor Library in New York and at several other libraries.

2d. Instead of "refuse," iron ores may be reduced in a similar manner, with mixing them with pig iron, the ores being thus used for decarburizing the pig iron either in their raw state or calcined.

3d. Instead of the above charge, pig iron may be omitted, and 350 to 450 lbs. of coke or other fuel, 300 to 350 lbs. of refuse, and 100 to 120 lbs. of burnt lime, or 140 to 170 lbs. of limestone, melted together, will produce finers' metal. The proportion of lime should be with mill scale one sixth, mill or balling furnace slag one third, pudding and finery slag one fourth of their respective weights of burnt lime.

4th. To produce metal from iron ore, 300 to 400 lbs. of coke, 300 to 350 lbs. of iron ore (broken small), and as much lime as would flux the ironstone in an ordinary furnace, are used.

5th. With proper proportions of flux, refuse may be used either with ironstone or iron ore, care being always taken to have a sufficient depth of scoria to protect the metal. "By having a hearth of sufficient depth below the twyre, part of the scoria may be run off, and a greater quantity of metal be obtained at one tapping."

6th. If the materials of the charge are sufficiently fusible the quantity of coke or other fuel may be diminished, or the amount of refuse increased, till "the proper degree of decarbonation" is obtained. Waste is thus lessened, since "the higher the iron is refined or blown, the less is the loss or waste in the subsequent manipulations of the forge."

7th. The metal may be kept protected by a sufficient depth of scoria "by drawing off the metal from below," instead of "allowing it to flow off above," thereby requiring less blast.

The furnace recommended for the smelting refinery is similar to a common blast furnace, but smaller, with a square or cylindric hearth, having a height of about twenty to thirty feet, six to eight feet in diameter at the boshes, two to three feet diameter at the top; the hearth being five or six feet high, and two to four feet in diameter.

NOTE.—*At this time of excitement about the Ellershausen process and the ore processes it has given rise to, it is interesting to remember that both ore and other oxygen-bearing substances were specified, to partially decarburize pig iron, over half a century ago—not in the puddling furnace, but in a sort of finery or first stage of puddling. The use of the ores is clearly stated in the 2d paragraph above.*

PARTIAL DECARBURIZATION BY MEANS OF AIR JETS, WITHOUT THE USE OF FUEL.

HILL, ANTHONY.—1817. August 5. No. 4,151.

Printed, 9d.

"Improvements in the working of iron." These consist "in causing crude iron while in a fluid state, howsoever and from whatever substance such fluid crude iron may have been obtained, to be exposed to and conveyed along with a strong current of condensed air or blast in such manner that it may be thereby minutely divided and dispersed, and expeditiously "blown and acted upon by the air." The patentee describes an arrangement of apparatus by which this object can be effected. A cullender of cast or wrought iron shaped like a bucket, being about eighteen inches in diameter at the top, and ten inches at the bottom, is supported in a case on the top of a wrought iron tube about thirteen inches in diameter, and eight feet long, called the "discharge tube," which is sunk into a well surrounded with water to keep it cool. At the top of the tube just beneath the cullender are apertures for the admission of a blast. The operation is performed as follows: The molten iron is poured into the cullender and falls through the holes into the discharge tube. At the same time a strong blast is injected into the tube in and among the divided particles of iron, which are thus subjected to its action during their descent into the well. The iron is collected at the bottom of the well, and at the end of the operation the water is discharged from the well, and the iron then "must be made into bar iron by puddling, reheating and rolling, or by any other known means."

NOTE.—*Anthony Hill is known to have been a practical iron worker, but how far he utilized this invention we have no evidence. He does not propose to decarburize the metal sufficiently to make it malleable, as Martien subsequently (September 15th, 1855) did, by less adequate means, viz: the blowing of air up into a stream of liquid iron as it flows in a runner. Neither of these inventions could accomplish anything further than refining iron preparatory to puddling, and Hill's has this advantage over Martien's—that it would work—in some limited degree.*

Hill's is the first recorded proposition to decarburize without the use of fuel to keep up the temperature, and it would appear to anticipate the claims of subsequent inventions as far as partial decarburization, without the use of fuel, is concerned. Bessemer introduced a radically new element—the MECHANICAL FORCE OF AIR *to keep the metal subdivided so that the oxygen could act on a vast surface of carbon at once, and thus burn it* FAST ENOUGH *to keep the iron liquid.*

CHARCOAL USED TO PROTECT THE BOTTOMS OF PUDDLING FURNACES.

HARFORD, RICHARD SUMMERS.—1822. January 9. No. 4,634.

Printed, 3d.

"An improvement in puddling." The improvement consists in using a layer of charcoal or charred carbonaceous matter, powdered or otherwise, to "protect the cast iron bottoms or floors of puddling furnaces" from the effects of the intense heat, and substituting charcoal for the substances usually employed, such as scoria or sand, which impart injurious qualities to the iron.

HEATING THE IRON TO BE PUDDLED BY THE WASTE HEAT OF THE PUDDLING FURNACE.

JONES, WILLIAM.—1822. October 18. No. 4,713.

Printed, 3d.

"Improvements in the manufacturing of iron." The invention consists in charging the puddling furnace with refined metal, pig or crude iron in a heated state, instead of putting the charge in cold. The heating operation may be performed either by the heat of the puddling furnace or in a separate furnace.

NOTE.—*This patent is partially or wholly anticipated by Gardiner's, in 1788. This important improvement has long been used in some establishments, and is just now coming into very extensive use in this country. It is found to effect a considerable economy of fuel.*

THE USE OF SALT IN THE PUDDLING FURNACE.

LUCKCOCK, JOSEPH.—1824. May 15. No. 4,956.

Printed, 3d.

"An improvement in the manufacture of iron." The improvement is stated to be the use of salt in certain quantities, ascertainable by experience, to be mixed with the iron in the state in which it comes from the blast furnace, and worked up with it in the puddling furnace.

NOTE.—*Anticipated by John Payne, 96 years before, as far as the chemical effect of salt in refining is concerned, though not used in the puddling furnace. Experiments are still making, and patents are still applied for in this direction.*

THE USE OF SALT AND POTASH, IN SPECIFIED PROPORTIONS, IN THE PUDDLING FURNACE AND FINERY.

LAMBERT, JOSIAS.—1829. March 30. No. 5,779.

Printed, 3d.

"Making iron." The invention consists in the application of two parts salt and one part of potash, in the blast, or refinery, or puddling, or balling furnaces. The mixture being applied to iron of inferior quality at a high degree of heat, is stated greatly to improve it.

NOTE.—*Payne also proposed, in 1728, the use of potash; Lambert, however, is the first to specify definite proportions.*

SPECIFIED QUANTITIES OF SALT, POTASH, LIME AND SALTPETRE IN PUDDLING.

LAMBERT, JOSIAS.—1830. February 4. No. 5,893.

Printed, 3d.

"Making iron." The invention consists in the use of a mixture of salt, potash and lime, or a mixture of salt, saltpetre, and lime, in the smelting, or puddling, or balling processes, in all or any of them. The proportions recommended by preference are two parts salt, one of potash, and two of lime, for the first mixture, to be used when the iron is of red short quality, and for the second mixture, two parts salt, one and a half saltpetre, and two parts lime, to be used when the iron is found to be "cold short." The mixture may be introduced in the furnaces at regular intervals, or combined with every change of materials. The mixtures are used in proportions, varying according to the qualities of the iron. The following are recommended: In the blast furnace, 25 lbs. to the ton of iron; in the finery, 20 lbs. to a ton of iron; in puddling, 18 lbs. to the ton; in the balling furnace, 18 to 30 lbs. per ton.

WATER AND AIR CASINGS FOR FURNACES—THE BOILING PROCESS—DISPENSING WITH THE FINERY.

HORTON, DANIEL, and HORTON, GEORGE.—1832. September 7. No. 6,299.

Printed, 1s. 10d.

"Improved puddling furnace." The invention consists in applying to the old puddling furnaces certain additions claimed as new, viz: hollow vessels or cases forming the ends and sides of the lower part of the puddling furnace, allowing air or water to circulate in contact with the inside casing of the puddling furnace, the object being to enable a very high degree of heat to be used in the puddling furnace without its being destroyed, the injurious effects being prevented by the circulation of air or water carrying off the superfluous heat. The use of this puddling furnace (which is fully described with drawings) enables the refining process to be dispensed with. On the bottom and sides of the furnace are strewed slag and cinder to the depth of about an inch or an inch and a half. These are melted and form a bottom, on which are placed broken pig iron and $\frac{1}{4}$ by weight of cinder and slag. The whole is then "raised to a higher degree of temperature than is usual in puddling refined iron, which will cause the pig iron to boil," "during which operation the same is to be well stirred" by the puddler "until the malleable iron is disengaged from the cinder." The heat, if necessary, is then to be damped off. The iron is to be balled, and the puddling completed in the ordinary way; and when the balls are withdrawn, the fluid cinder is run out, and a fresh charge is put in. Malleable iron is thus produced direct from the pig.

NOTE.—*Water casings, backs and frames have been the subjects of many subsequent patents, new, doubtless, in detail; but here is the first record of the practice, and it is quite comprehensive and complete.*

Although commencing with pig iron is specified in former patents, the finery was universally used at this time as a preparatory process.

The boiling process was introduced, apparently, to avoid the finery—to decarburize faster. It is now used to make a better quality of iron.

A SHOOT TO CARRY MELTED IRON FROM THE BLAST FURNACE TO THE FINERY.

GUEST, JOSIAH JOHN.—1833, January 31. No. 6,379.

Printed, 3d.

The invention consists in affixing to the blast furnace an iron shoot or channel, and running the molten metal from the blast furnace direct into the refinery furnace (which is placed near thereto), where the iron is refined in the usual manner.

SPECIFIED QUANTITIES OF OXIDE OF MANGANESE, SALT AND CLAY, IN MAKING MALLEABLE IRON.

SCHAFHAUTL, CHARLES.—1835, May 13. No. 6,837.

No specification. See Repertory of Arts, Vol. IV, new series, p. 334; and Newton's London Journal, Vol. VII, p. 341.

"Manufacturing malleable iron." The specification of this patent appears to have been stolen.

From the following references (Repertory of Arts, Vol. IV, new series, p. 334; Newton's London Journal, Vol. VII, p. 341), it seems that the invention consisted in the use of black oxide of manganese, 1¾ lbs.; common salt, well dried, 3¾ lbs.; potter's clay, well washed, 10 oz. The ingredients are well mixed and ground fine, and fused with about 3¾ cwt. of pig iron in the boiling oven. The color of the flames will indicate the progress of the fusion. The mixture being, by preference, introduced in three portions, the result will be a good soft iron. To produce a harder iron, three or four shovelfulls of roller refuse and cinder from the balling furnace are added, and only half the quantity of manganese employed. Less quantities of manganese and more of refuse and slag will produce a harder iron.

NOTE.—*The use of manganese was first specified by Reynolds, in 1799. Schafhautl is the first to particularize proportions, which, by the way, are not very different from present practice in some localities. Manganese is now generally employed in the puddling furnace, in the shape of Franklinite pig iron, or spiegeleisen—the carburet instead of the oxide—and is found of great advantage when the irons treated are sulphurous. It is indispensable to making good puddled steel from most of our irons.*

PUDDLING WITH THE USE OF PULVERIZED IRON ORE.

MUSHET, DAVID.—1835, October 22. No. 6,908.

Printed, 6d.

"Manufacturing bar iron or malleable iron." The specification commences by giving a detailed account of the refinery and puddling processes, and the terms employed therein, and of the different qualities of cast iron. It then proceeds to describe the improvements patented, which consist in mixing finely-powdered iron ores of rich qualities with the iron while being puddled in the puddling furnace. Sometimes powdered charcoal is mixed with the powdered iron ores. The mixture is added in small doses, and promotes the fermentation of the iron, and causes it sooner to be "brought to nature." It also enables crude iron to be used without being refined, and produces a bar of improved quality and greater weight than the old processes. A charge of about 450 pounds of crude pig iron, varying in quality from bright grey and mottled to white, according to circumstances and the judgment of the manufacturer (No. 2 grey iron foundry metal will produce excellent bar iron) is employed; when it begins to melt, and is fit to be stirred by the puddler, a dose of about two pounds of powdered ore, or ore and charcoal, is sprinkled on the iron, and well stirred up with it. The doses are gradually repeated as they are absorbed, until about forty pounds of powdered ore (or one-eleventh by weight of the charge of crude pig iron), have been sprinkled on the fermenting iron. The puddling process is carried on meanwhile in the usual way. If charcoal is mixed with the powdered ore, it should be wetted. By this process, about twenty hundredweight of puddled bars are produced from twenty-one and a half hundredweight of crude pigiron of as good quality as would be obtained from ordinary refined metal. If refined metal or "plate" be used instead of crude pig iron, to a charge of 450 pounds about twenty-five pounds of powdered ore should be used, and twenty hundredweight of puddled bars are produced from twenty and three-quarters hundredweight of refined metal or plate. Other proportions and particulars are given according to the quality of the materials employed.

NOTE.—*David Mushet was the very best authority on the iron and steel manufacture at this time. Like other men of large ideas and experience, he sometimes patented or suggested very novel changes, which, although very reasonable, also, had not been worked out in practice. In this case, however, his specification was obviously drawn up after the facts had been fully developed.*

Thirty-four years ago, Mushet published the fact that stirring fine ore into iron during the process of puddling IMPROVED THE QUALITY AND INCREASED THE YIELD—*a fact that some of our iron makers have not yet found out. Coarse ore for fettling has long been used, especially in the works about Troy; but the practice is not so common in Pennsylvania and the West. Indeed, the Troy iron makers consider the Ellershausen process a greater improvement on the Pittsburg practice than on their own. But stirring in fine ore has just begun to be practiced regularly. Mushet specifies about 10 per cent of ore; as much as 30 per cent (what Ellershausen uses) has lately been used in the puddling furnace during a fortnight's steady work, with a very great economy of fuel and time, and with an improvement of quality.*

Some 20 years ago, the experiment of mixing charcoal with the ore, as here suggested by Mushet, was tried at a large American works with very good results. The practice has lately been revived. The use of carbon to aid decarburization can be explained on the ground of promoting a higher heat throughout the mass. The more carbon there is in Bessemer pig iron, the more easily is it removed; the rapidity of combustion is the great end to be sought.

A good many inventions are from a quarter to a half a century ahead of the times. The Stevenses, of Hoboken, developed or suggested nearly every feature of modern iron-clad warfare twenty years before they were taken up by Governments. In fact, Col. John Stevens made drawings of an iron-clad ship for the defence of New York in 1812, which was 43 years prior to the first use of iron-clads in naval warfare. Mr. Mushet was equally in advance of the times, not only in his practice mentioned above, but in other directions to which we shall have occasion to refer.

MECHANICAL PUDDLING.

SCHAFHAUTL, CHARLES.—1836, June 13. No. 7117.

Printed, 9d.

"Apparatus for puddling iron." The specification and drawings describe an apparatus for working the stirring rabble, and giving it the necessary longitudinal and transverse motions in the puddling process.

NOTE.—*Considering the fact that this process is likely to come into use soon in this country, these old patents (this is the first record on the subject), are likely to be interesting, and we commend their perusal to the one hundred and one geniuses who will apply for rabble moving contrivances as soon as the thing is likely to be in demand.*

THE DRYING OF PAINT.

From a paper by Charles Tomlinson, F. R. S., read at the Society of Arts.

(Continued from page 261.)

Every one knows what is expected of good paint. In the first place, it should be sufficiently liquid to spread under the brush, and sufficiently viscous to adhere to the surface, even though it be vertical, without running, or becoming unequally thick in different places. In the second place, it should become solid within a reasonable time after being applied. Thirdly, the solid should adhere strongly to the surface.

We have seen that lead and zinc paints become solid by the absorption of atmospheric oxygen. But as pure linseed oil also becomes solid by exposure to the air, the drying of the paint is not due to the presence of a dryer, or of the oxide of lead or of zinc. It is true that the dryer acts by increasing the absorptive power of the oil for oxygen gas. The lead and zinc oxides have also drying properties, and we must not neglect the influence of the surfaces that are to be painted. Paint dries at different rates on glass, wood and metal; it dries better on some kinds of wood or of metal than on others, of course under similar conditions of experiment.

Drying on Glass.—Surfaces of glass were coated with linseed oil, also with the oil containing a little white antimony, and with the same compound with the addition of a little litharge. The linseed dried quickly, the antimony compound not so quickly, while in the third compound the presence of the litharge seemed to neutralize the retarding effect of the antimony. The following table shows the results:

	Linseed oil.	Linseed oil and oxide antimony.	Linseed oil and litharge dryer and oxide antimony.
	Days.	Days.	Days.
First coat dried in...	17	26	21
Second coat dried in..	17	8	9
Third coat dried in...	9	9	2
Total	43	43	32

It appears from this table 1. That a glass surface does not allow the paints to solidify so readily as a surface formed of the solid oil or paint. 2. That the antimony oxide is antisiccative, which effect is corrected by the litharge. 3. That in the second coat the glass seems to be still exerting a retarding action on the oil, but this is not so evident in the antimony paint. 4. That the influence of the litharge dryer is evident in reducing the time required for the drying of the third coat. This influence seems to depend not only on the presence of the litharge dryer in the viscid paint, but also on its presence in the solid surface on which the fresh paint is laid.

Drying on Oak.—The influence of the kind of surface employed on the drying of paint is well shown in the case of oak. On oak surfaces stained brown, three coats of linseed oil took forty-six days to dry, oil with a litharge dryer seven days, oil with a manganese dryer still less time. It was also found that linseed oil and white lead and linseed oil and white zinc dried more quickly with a manganese dryer than with a litharge dryer. On a surface of clean oak the first coat of oil took a very long time in drying. On the twenty-second day it was soft and pasty beneath the surface; the oil had sunk into the pores of the wood, and thus prevented it from absorbing the oxygen required for its solidification. This explains why oil dries more quickly on a painted wooden surface than on a porous one. On a porous surface the dryers seem to act with great effect, probably from covering the wood and preventing the oil from sinking into the pores. Their influence is shown in the following table:

	Linseed oil and white zinc.	Linseed oil and litharge dryer and white zinc.	Linseed oil and manganese dryer and white zinc.
	Days.	Days.	Days.
First coat dried in...	66	6	5
Second coat dried in..	6	5	3
Third coat dried in...	6	5	3
Total	78	16	11

This also shows that a surface of linseed and white zinc allows the paint to dry much more rapidly than a surface of porous wood does. A similar effect is produced when the paint is laid on an old surface of paint. The paint itself also becomes more siccative under the influence of time and atmospheric exposure.

It appears from experiment that paint dries more quickly on poplar than on oak, and more quickly on pine than on poplar. In the experiments on metallic surfaces the most remarkable results were obtained on lead. The first coat of linseed oil dried very quickly on this, as also the first coats of lead paint and of zinc paint. The zinc paint dried first, then the linseed oil, and lastly the lead paint. The zinc paint, however, tended to retard the drying of the subsequent coats. A newly scraped surface of lead acted more energetically than one that had been tarnished by exposure to the air, but the lead covered with one coat lost its influence in hastening the drying of the subsequent coats. The first coat of oil on bright lead was only ten hours in drying. In short, we get this remarkable result, that lead is siccative with reference to pure linseed oil, while white lead itself, a siccative body, is anti-siccative with respect to linseed on metallic lead.

Summary of Results.—The influence of various metallic, vitreous and wooden surfaces is thus summed up by M. Chevreul:

First Coat—*On Copper.*—Oil dried more slowly than both oil and white lead, and oil and white zinc.

On Brass Wire and Zinc.—Oil dried as rapidly as oil and white lead, but more rapidly than oil and white zinc; but on the brass wire the drying was more rapid than on zinc.

On Iron.—Same results as on zinc; but oil and white zinc dried more quickly on iron than on zinc. This is analogous to the fact noticed with lead. The oil and white lead dried more slowly on lead than did the oil and white zinc.

On Porcelain and Glass.—Oil dried a little more quickly than oil and white zinc, and oil and white lead a little more quickly still.

On Plaster.—The oil and white zine paint dried in about equal times.

On Poplar and Mountain Ash.—Oil dried more slowly than oil and white lead, and also than oil and white zinc.

Three Coatings—*On Copper, Brass Wire, Zinc, Iron, Lead.*—Oil and white lead dried more quickly than oil and white zinc. This was also the case on porcelain, glass, plaster, poplar, and mountain ash. In the case of the woods, linseed oil was found to dry more quickly on ash than on poplar, and more quickly on poplar than on oak.

Effect of Temperature.—Some of these surfaces may, however, be regarded as indifferent, as respects their influence in quickening or retarding the drying of paint; but the temperature and other circumstances modify any general conclusions that may be drawn on the subject. Paint dries more quickly at from 77° to 82° Fah., than from 59° to 64° Fah., other things being equal. This explains why, in practice, the proportion of dryer varies with the temperature. In winter it is customary to add from three to nine, and even ten per cent of dryer to the linseed; in summer not more than half, one and a half, or two per cent, and it may even be left out altogether in the last coat.

Effect of Dryers.—The drying property of linseed oil is nearly always increased by the addition of white lead, and in most cases by that of white zinc. If the compound be not sufficiently siccative, it can be made so by the addition of a dryer, whether of litharge or of manganese, due respect being paid to the varying conditions of the surface, number of the coats, whether first, second or third, temperature of the air, and the amount of natural light present. But the influence of the lead or manganese dryer, as will be gathered from the foregoing details, is not so important as is generally imagined. It can be dispensed with in the second and third coats, and even in the first if the temperature of the air be favorable. Linseed oil by exposure to light and air loses its yellow color and becomes siccative, so that it can be employed alone with white lead or white zinc without detriment to their purity. If white zinc be associated with the sub-carbonate of zinc, the dryer may be dispensed with altogether.

Lustre of Paint.—Paint owes its lustre and smoothness to the oil alone. If oleic acid were mixed with metallic oxides in such proportions as to form solid chemical compounds, and the acid were to pass quickly from the liquid to the solid state, the result would not be a smooth, uniform oleate; but when the drying oil passes slowly into the solid state, in consequence of the gradual absorption of oxygen, and the changes pointed out by Mulder, the very slowness of the process allows the oily molecules to arrange themselves into a symmetrical compound, which would be transparent were it not for the opaque particles of the white lead imprisoned in the compound. If these opaque particles are not in excess, the molecular arrangement is such that the paint dries into a surface that is lustrous, and even brilliant, in consequence of the mirror-like reflection of the solidified oil.

EFFECT OF TURPENTINE.—This substance is added by painters, in order to diminish the viscosity of the paint, and to allow it to spread more easily under the brush. If the surface is to be polished, a large proportion of turpentine is used; if it is to be varnished, as much turpentine is added as will render the paint very fluid, but not too fluid to work with; if the paint is to be very durable, and it is to be neither polished nor varnished, only a small proportion of turpentine is to be added. As turpentine dries to a great extent by evaporation, one of its chief uses is to hasten the drying of paint. Thus, three layers of linseed oil on glass dried in twenty-five days; but when about thirty per cent of turpentine was added to the oil, the mixture dried in twenty days. This drying effect is promoted by a previous exposure of the turpentine to the air. When both oil and turpentine have been previously exposed, the drying takes place still more quickly. Exposure to air has a similar influence on the other ingredients of paint, even on the white zinc.

OTHER DRYERS.—This exposure in the case of turpentine favors the combination with atmospheric oxygen and the consequent resinification of the liquid. Exposure in the case of a porous body like white zinc may also lead to the physical absorption of oxygen, and thus hasten the drying. If this physical effect were really obtained in the case of white zinc and white lead, Chevreul thought it likely that the presence of other solid bodies in the paint might have a similar effect. But before putting them into the paint, their influence as surfaces was tested. When linseed oil was laid on white lead, three coats dried in seven days; but on sulphate of zinc they occupied eighteen days in drying, twelve being required for the first coat and two for the second; white lead is therefore more siccative than the zinco-sulphate. In both cases the first coat acted as a dryer to the second. When a mixture of sulphate of lead and white lead was used as the surface, the oil dried almost as quickly as on white lead alone. It has already been shown that the addition of the litharge and manganese dryers made the linseed oil dry more quickly; that is, it became more capable of absorbing oxygen from the air. It is remarkable that this absorptive power is increased by the addition of solid bodies, such as sand. Linseed oil mixed with white lead dries more quickly than the oil alone, so that white lead is a dryer or siccative. Oil mixed with sulphate of lead dries very slowly; but a mixture of oil, sulphate of lead and white lead, dries as quickly as oil mixed with white lead only. Hence the presence of white lead confers extra drying power on sulphate of lead. Carbonate of zinc acts as a dryer, when added to oil or white zinc; and the mixture dries more quickly than oil mixed with white zinc only. Oil mixed with zinc carbonate sets more rapidly than with zinc white; but it forms a semi-transparent, not an opaque paint. As zinc carbonate renders oil and white zinc more siccative, it might be substituted for the manganese dryer, which has the disadvantage of imparting color to zinc white. Two paints were prepared, one consisting of 100 lb. of linseed oil, 75 lb. of zinc white, and 25 lb. of zinc carbonate; the other of 98 lb. of the oil, 2 lb. of the manganese dryer, and 100 lb. of white zinc. With each of these paints a door was painted. Four hours after they had been applied both paints appeared to be equally set; but the surface coated with the first paint was whiter than that coated by the second; the whiter paint was, however, the less adherent.

ECONOMICAL RAILWAYS.

AMERICAN FEATURES — THE NARROW GAUGE — IMPROVED LOCOMOTIVES — WELL FILLED TRAINS.

The interest of the profession and the public, in this subject, is on the increase, especially in England. Although at the first glance the idea of light, cheap railways, seems an approach to the American system, yet upon investigation it will appear that only one or two features of construction and working, that are distinctively American, are advocated for the guidance of English constructors and managers. Let it be always and distinctly understood that the "Light Railway" movement in England is not an indorsement, in any degree, of the American counting-room system of *bad* railways—poor iron, cheap machinery and rough roads. On the contrary, the improvement of locomotives, running gear and permanent way, are among the chief features of the proposed reform.

The features that might be called American, as proposed for new British railways, especially in the rural and mining districts, are, first, following the surface of the ground —going over and around hills rather than through them—up to certain limits of curvature and gradient, say one in 40 and five chain curves; second, the use of a single track worked by telegraph; third, filling the trains with paying load. In these respects even we might improve. But in the other proposed economies we need as much instruction and reform as the English, viz: in the narrow gauge for branch lines of light traffic, and especially for under-ground city lines, where every additional foot of surface bought, and cutting made, tells largely on the cost; and in a better system of running gear for all lines; in articulated rolling stock, and in the utilization of weight for adhesion.

In a former article* we considered the excessive and unnecessary cost of English lines—a cost made up of parliamentary expenses, land damages, and heavy earthworks and engineering structures, to secure straight, level roads. We now propose to consider some other features in the proposed reform, compiling from the standard authorities before quoted: First, the use of single lines.† These, if worked by telegraph upon the block system would be equally safe, and in all respects as sufficient as double lines. It would be an active traffic that required twenty-four long and well filled trains each way daily, yet this is but one an hour in each direction, so that the rails of every mile of a double line would be unused for about twenty-three hours of the twenty-four. A proper adjustment of trains, proper care, and the indispensable aid of the telegraph, render a single line as safe as a double line, it being understood that the trains are not so numerous as to exceed say two each way in the hour. The extra cost of a second line of way, including extra width of cuttings, embankments, viaducts and tunnels, cost of land and cost of permanent way, cannot be taken as much less on the average of English lines than £5,000 per mile, upon which the interest charge at five per cent is more than 1s. per train mile for eight trains each way daily, these trains easily accommodating a daily traffic each way of 1,000 passengers and from 500 to 1,000 tons of goods. Single lines form the majority of the Prussian railway system, which is worked with fewer accidents than almost any other in the world. The single line system in the United States, when worked by telegraph, has not proved unsafe; the greater number of "accidents" on these roads resulting from bad construction and attendance.

The narrow gauge is advocated by various authorities, among others, Mr. Hulse,* as follows: There are strong reasons for preferring the 3½ft. to the 4ft. 8½ in. system for local railways. The rails of the former do not exceed 40lb. to the yard; tunnels and bridges of a height not exceeding 10½ft. may be employed; open cuttings of much smaller dimensions; and curves may be used of a radius of only two chains, the locomotive engines need not exceed 15 tons weight; carriages 5 tons weight; and on no driving wheel would there be more than three tons. Whereas on the 4ft. 8½in. system the rails are 80lb. to the yard; tunnels and bridges 24ft. wide, 16ft. high; open cuttings in proportion; curves not less than eight chains radius; locomotive engines, 30 tons weight; carriages, 8 tons; minimum load upon each driving wheel, 6 tons. The short curves admissible on the narrow guage avoid to a great extent the destruction of property, villa residences, etc.; that is in passing by, instead of through them. The minimum radius of the curves and minimum height of headway admissible in each system are the most important features to be considered in deciding upon the best system of railways for towns which have canals, rivers, existing railways, a labyrinth of sewers, gas and water pipes ramifying throughout. Another important feature to be considered, of course, is the question of cost. The 3½ft. system, it is estimated, will cost less than two-thirds as much as the 4ft. 8½ in. system, and may be worked at a correspondingly small expense.

It may be asked why not adopt a 3ft. or even narrower system. The answer is that the 3½ft. system is already largely adopted in Queensland, Ceylon, Norway, Belgium, and other places, and with complete success. In designing the carriages for the local line, the 3½ft. gauge is found to give ample accommodation. The carriago which promises to be most suitable is what may be termed of the omnibus type, with seats arranged on each side and a longitudinal passage, say

* Van Nostrand's Magazine, Vol. I, No. 3, p. 243.

† See also a list in the "Railway Notes," on a following page, of particulars and results of narrow gauge lines.

*Address of Mr. W. W. Hulse, President, before the Manchester Institution of Engineers.

30in. to 36in. wide down the middle, with doors opening inward at the ends. The leading dimensions are 20ft. long, 6ft wide, and 6½ft. high inside. Carriages of this size would accomodate 24 passengers, twelve on a side, and give over 30 cubic feet of space to each. It might indeed be found desirable to adopt even a 2ft. gauge in some districts for cheapness, as has been done in North Wales, where the Festiniog Railway has a gauge of 23in., locomotive engines under 8 tons weight, and over this railway of thirteen miles in length, were carried in 1865, 2,500 passengers, 11,000 tons of general merchandise, and 90,000 tons of minerals, yielding a profit, it has been stated, on the capital outlay of 26 per cent.

Another authority says on this subject: As a rule, we are not favorable to the adoption of narrow, or more properly, small gauge railways; they appear, as it were, to constitute a bar to the future development and extension of commerce and traffic. We would greatly prefer to witness a large and important undertaking, designed and executed upon a scale somewhat exceeding the proportions actually necessary, than to witness it carried out in a manner that barely sufficed to meet the exigencies of the moment. There is a medium between building for posterity—between concerning ourselves about the probable state of our coal fields after the lapse of half a dozen centuries—and constructing works so that they should be, in the main, capable of answering their intended purpose for the next fifty years. To each generation belongs its own duty of construction, reconstruction, demolition and alteration, and it is unjustifiable to incur a heavy extra expense in order that "a thing may last for ever." Are we, then, awaking to the conviction that we have spent millions upon railways in endowing them with properties that are self-destructive? One of the reasons influencing Brunel in his recommendation of the seven feet gauge was, that by thus enlarging the base of the rolling stock, increased stability would be obtained, and a speed ensured higher than that which would be compatible with safety upon a narrower track. Time has shown this reasoning to be fallacious; the trains upon the Great Western do not run faster, or, practically, with greater security than those upon other lines. Similarly, by its own supporters, the 4 ft. 8½ in. gauge was considered the narrowest that could be employed with safety, bearing in mind the great velocity that was expected would be ultimately attained upon it. It is needless to mention that the velocity anticipated never has been attained on either of the gauges. Both Stephenson and Brunel, it is well known, contemplated the probability of running trains at a speed of a hundred miles per hour, whereas the average maximum reached is barely half this amount, and the minimum is something less than what was the usual pace of the old "fast coach." It must not be understood that we consider this conclusion (favoring a narrower gauge) to apply to all our railways. A line similar in extent and importance to the London and North-Western, constructed upon a gauge of three feet or three feet and a half, would be a miserable failure, but a double line upon a similar width of track, to convey the coal traffic from Newcastle to London, might not only present a different appearance, but prove a very remunerative speculation.

We have too long adhered to a false system of locomotive construction. While greatly overloading the driving wheels of our engines, we throw away from one-half to two-thirds of the total adhesion weight. We also make needlessly large driving wheels, often employing 6½ft. to 7½ft. where 5ft. to 6ft. would answer the fair requirements of traffic, and permit of smaller cylinder and less weight of working machinery. We can see no solution of the problem of economical locomotives except in the double bogie system. In these almost any length of total wheel base may be had without straining the way or inducing excessive friction; the weight is equalized on all the wheels and the weight per wheel kept down to 4 or 5 tons, instead of, as is now often the case, 7 or even 8 tons. Fairlie's engines are also rid of the burden of the lumbering tender, a great 12 or 14 ton monstrosity, with the additional weight of, say, a ton of coal, and from 5 to 10 tons of water, water which should be "picked up," in quantities of one or two tons only at a time, as wanted, from Mr. Ramsbottom's troughs. A double bogie tank engine having eight 5ft. wheels, and weighing but 36 tons, the wheels driven by two pairs of 14 in. cylinders, with a stroke of 2ft., would, with a very moderate steam pressure, pull a train of a gross weight of 300 tons up a two mile incline of 1 in 60, at the rate of 20 miles an hour, a work corresponding to nearly 800 horse power, during the six minutes of the run, in thus surmounting an elevation of more than 175ft. Such engines, without excessive total weight, would have a power sufficient to deal easily with trains of much greater weight than the present, upon gradients and through curves seldom met with on our own old, costly, "first-class" lines.

A farther economy should consist in running fewer, slower, and better filled trains, thus dividing the expenses per train among a greater number of passengers or tons of goods in that train. It was not long since stated that the London & North-Western, Great Northern, Great Western, and Midland Railways together run fifty-two passenger trains daily between London and Manchester! So far as through traffic is concerned, three or four each way daily should serve every reasonable requirement. Railway promoters and engineers must yet awake to the fact that the most profitable and useful railways are those made and worked for the great paying lower class, as distinguished from the far less numerous and far more fastidious upper class. The former do not require either very fast or very frequent trains. An excursion train shows with what they are willing to put up. And a thousand passengers in a train, paying each a farthing a mile, £1-0-10 per train mile, is about the most profitable load an engine can draw, unless it be a bullion train, paying, it may be, £4 or even £6 per mile, as has been the case on the South-Eastern line.

In cases, however, where there is a large and constant stream of passengers, railway carriage can be cheapened enormously, with abundant remuneration to the carrier. We can best illustrate this by contrasting the fares on the Metropolitan Railway with those which are charged and found quite unremunerative upon country branch lines. From Notting-hill to Moorgate-street and back, a distance of twelve miles, first-class passengers are carried for 1s.; second, 9d.; third, 6d.; being at the rates of 1d., and $\frac{3}{4}$d., and $\frac{1}{2}$d. respectively per mile; yet that line cost an average of over £500,000 a mile to construct. But on a branch country line, the rates may be 3d., 2d., and 1d., a mile, and the cost of the line only £10,000 per mile, yet no remuneration will be obtained.

Land damages are often a most unjust tax upon railways and the public. It should require no parliamentary contest to make a railway more than to make a highway or to open a street. And so far from landowners being "compensated" at extravagant rates, the benefits, generally very great, which railways confer upon their property should be considered and taken into account. The eight acres of land taken for a mile of railway may be worth far less, valuable though it be, than the benefit which the railway itself confers upon the adjacent hundreds of acres. The question arises, are new cheap lines required on routes where the present costly lines exist. The older lines were constructed at immense cost for a speed for which a great majority of the public are unwilling, if not unable, to pay. And it does not answer the question nor the purpose to say that they can have as slow a speed as they choose on the existing lines. So they might; but, unless the great capital charge upon these lines is in part sacrificed, the slow speed will not after all be a cheap speed to the passengers. Unless the companies are prepared to do this—and it is certain that they are not—the public have a good right to call out for free trade in railways. Even a war between competing companies would be for the time to the public benefit, and it is certain that the company having the smaller capital burden would have the advantage in any contest. Its line may have steeper gradients and sharper curves, involving a somewhat greater charge for locomotive power and maintenance of way; but there would not be the long tunnels, the lofty viaducts, the grand metropolitan approaches, and the magnificent termini to pay interest upon.

In conclusion, it is tolerably certain that, with the cheaper lines and more economical mode of working, taken together, nearly one half of the present rates of fare might be saved. Such economy is not without precedent. English "railway men" are mortified to read in our Continental Bradshaw as follows: "The railway system (of Belgium) was adopted as early as 1833, and at the present moment no country in Europe is better provided with railway accommodation than this industrious and prosperous land. There is not one town or village of any importance without its railway communication. The fares are lower than in any other country; for long distances not exceeding $\frac{1}{2}$d. a mile first class, $\frac{1}{3}$d. second class, and $\frac{1}{4}$d. third class—one-fifth of the rate charged in England." Yet the Belgian lines are profitable to the state, and that too, nothwithstanding that all the elements of necessary cost, whether of construction or working, are as great as in England, excepting only the cost of labor, and the salaries of officials. There is no difference, in principle, between the English and Belgian systems of railway construction, nor in the rolling stock employed.

DIRECT ACTING STEAM PILE DRIVER.

SYSTEM PATENTED BY M. J. CHRETIEN, PARIS.

Translated from "Le Génie Industriel."

In order that pile driving may be effected rapidly and economically, certain conditions must be satisfied, the chief of which we will indicate. Of the first importance is the rapidity of the blows; next to that is the weight of the ram, and lastly the height of the descent. At first, it might seem that with a given fall and weight of ram, the number of blows would be the same, whether struck at long or at short intervals. Practice, however, shows the reverse of this to be true, and it is not difficult to account for the difference in the two cases. For example, it might be necessary under certain circumstances, to give 100 blows at the rate of four or five per minute, in order to sink a pile to a given depth, while it is well known that at the rate of fifteen or twenty blows per minute the amount of drift would be considerably greater; in other words, fewer blows would be required to produce the same result. The difference is such that in certain soils the results might vary in the ratio of one to two. It is easy to see that if a pile, which has received a series of blows, is allowed to remain undisturbed for a sufficient length of time—or possibly only a few minutes—the earth which has been forced aside by the entrance of the wood settles back around it, and ultimately sets. The result of this adhesion is an increased resistance to driving. But if the blows are repeated very rapidly, the earth, which is more and more thoroughly displaced by each successive stroke, has not time to settle back or to adhere. The pile is, as it were, sunk into a hole in the ground, and the work is but little more than that requisite to drive the point. These effects are most decided in soft ground, in sand, and in works under water. Heretofore, in prescribing the weight of the ram and the number of blows, engineers have merely indicated the point at which the pile refuses to sink lower; but in view of what has been said we think they should no longer neglect the time during which the blows should be given.

The weight of the ram is of considerable consequence, but its importance should not be exaggerated, especially when it is possible to regulate the fall and velocity. A heavy ram, falling from a great height, gives a powerful shock, but beyond certain limits the effect produced ceases to be proportional to the weight, and besides, there is the disadvantage of exposing the pile to splintering, which should by all means be avoided. Any weight in excess of 1,000 kil. is injurious rather than useful, and in general it is not advisable to exceed 800 kil.

The height of the fall is the most variable element, and the best driver is the one which will strike both light and heavy blows with rapidity. There is no minimum, since in some cases it is necessary to begin by striking as lightly as possible; but there is a maximum, for no part of the force of the blow should be expended in splintering or even in sensibly altering the wood. A descent of five meters is the greatest which it is well to employ when the blows can be struck rapidly enough.

The pile driver invented by M. Chretien completely satisfies the conditions just laid down. It is constructed upon the general plan which that engineer has already applied to direct acting cranes and lifts. Its simplicity is such that all deterioration is well nigh impossible, and its maintenance is most economical. By comparing it with the direct acting steam-crane just mentioned, or with the steam-hammer, it will be seen that it is practicable to strike very light blows, and also to strike rapid ones up to a blow per second. The rapidity of movement should be limited only by the boiler power, which should be proportioned to the work which it is desirable to accomplish in a given time.

[The most important peculiarities of this machine are, first, the peculiar method of applying the power to the weight. The chain passes from the ram over a grooved roller at the top of the guides; thence downwards around a second grooved roller, situated in a frame attached to the end of the piston-rod; thence upwards again over two more rollers at the top of the guide-frame, and finally is made fast around a windlass within reach of the engineer. Second, the steam cylinder is of great length—equal, in fact, to one-half the extreme rise of the ram—and works nearly vertically. The mechanical principle involved in raising the weight is that of the pulley in its simplest form; the power being applied *between* the two ends of the chain, and the weight being at one end. Hence the rise of the weight will be twice the amount of movement of the piston.]

The workman who manages the driver has only to move a single lever, and each movement of the hand corresponds to a blow.—As fast as the pile sinks he unwinds the chain from the windlass, thus regulating the fall by the depth to which the pile has been driven. At the same instant he lowers at pleasure the wedges which limit the rise of the ram, and all without loss of time.

There are two ways of driving with this machine—first, by not loosening the ram from the hook, in which case the block descends with the grapnel and chain, and strikes lightly and rapidly; second, by long descents, in which case the ram, arriving at the top of the slides, detaches itself, falls, and is raised as soon as the grapnel takes a new hold.

Finally, the same maneuver serves for putting the pile in position (*à la mise en fiche*). Unwinding the chain from the windlass and fastening the grapnel directly to the pile, the mechanic draws it in by a few strokes of the piston and by reversing the windlass.

It was at the works undertaken by the city of Paris near the Pont de l'Alma that this pile driver was first tried. Its success has been so satisfactory that the engineers and contractors who have observed its workings have ordered them.

MODERN ENGINEERING.

It would be difficult to condense Mr. McAlpine's excellent paper on this subject, lately read before the American Institute. The following points, however, are of peculiar interest:

Since 1829, the locomotive has increased from four to 40 tons in weight, and from fourteen to 60 miles per hour in speed. Then grades of 50 feet per mile were the maximum, now those of 440 feet at Mont Cenis and 528 on the Baltimore and Ohio, have been used. Forty years ago Horatio Allen had to mount the foot-board of our first locomotive himself, now 15,000 are daily whirling over 40,000 miles of railways in this country alone.* The Erie Canal, originally built for vessels of 60 tons, has just been enlarged for those of 250 tons, and its increasing traffic already demands an enlargement for vessels of 1,000 tons. Of the traffic of the great West it now carries more than all of the great trunk lines of railway between the St. Lawrence and the Potomac. One canal boat carries more tonnage than a freight train, and the Erie Canal brings daily to tide water more than five times as much tonnage as the New York Central. Its tonnage exceeds that of all the foreign commerce of New York. The materials used in its construction exceed in quantity those required for the 2,000 miles of the Pacific Railway.

The Niagara and Cincinnati wire suspension bridges by Roebling; the Havre de Grace bridge, of wood, by Parker; the Schuylkill bridge of cast iron arches, by Kneass; and the Victoria iron girder by Stephenson, are among the most noted bridges. In submarine works in this country, the most remarkable are the piers of the Potomac and Croton aqueducts, of the Havre de Grace and Harlem bridges, and the founding of the United States Graving Dock, at Brooklyn. The aqueducts and graving dock were founded by means of coffer dams, the Havre de Grace bridge by means of iron caissons, and the piers of the Harlem bridge are composed of large cast iron columns or hollow piles, driven by the newly discovered pneumatic process. A mass of metal of a ton weight was unknown before the Christian era. Now those in cast iron up to 150 tons, in wrought iron to 40 tons, and in steel or bronze to 25 tons, are made in any desired forms, and turned or bored with the most perfect accuracy.

The works of the ancients are often referred to as excelling, in magnitude, accuracy and beauty, those of modern times. This view is in part at least, quite erroneous. Their works were generally for useless purposes, although there are many exceptions, such as their canals, water works, military roads and bridges. The stones in the temple of Baalbec are the largest of any building in the world save one. They range from 1,200 to 1,275 tons. In one at St. Petersburg they are $\frac{1}{5}$ larger. The monoliths of Egypt are from 200 to 300 tons, and a few of 700 tons. The obelisk of Luxor, now in Paris, weighs 250 tons. The "goodly stones" of the temple at Jerusalem weighed 350 tons each. The probable method of constructing the great Pyramid of Gizeh, was by means a mound of earth and an inclined causeway; when the structure was completed the earth was removed. This

* It is estimated that there are over 40,000 locomotives in all countries.—*Ed.*

pyramid contained 6,500,000 tons of stone, and the embankments required 50,000,000 tons of earth. All of the masonry of the Erie Canal amounts to but one-third of this, and all of the earth moved for the Pacific Railway amounts to but that used instead of scaffolding for this pyramid. It required the labor of 500,000 men for thirty years, and cost $5,000,000,000. A modern engineer would construct such a work for $100,-000,000, and use a tithe of the men. The Coliseum at Rome was but one-third of the size of the London Exhibition building, and but one-sixth of the Paris building. The tonnage of the Ark was 12,000; of the show ships built by Ptolemy somewhat less, and of the Great Eastern 22,500 tons. Some of the modern men-of-war have nearly 9,000 tons displacement, and our passenger ships 3,000 to 5,000 tons. The largest steam engines in the world are those used in draining the Haerlem Mere, with steam cylinders of twelve feet diameter and fifteen feet stroke, driving eight pumps of 63 and 73 inches diameter, and ten feet stroke. These three engines were capable of delivering a volume of water six times as great as that of the Croton. The next largest pumps are those of the Graving Dock at Brooklyn, of one-third of the capacity of those at Haerlem Mere. The steam engines next in size are those of the Bristol and Providence steamers, with cylinders of nine feet two inches diameter and twelve feet stroke. Seven of the most noted modern engineering works to contrast with the seven wonders of the ancient world, are the Thames Tunnel, the Great Eastern steamship, the Atlantic Cable, the Britannia and Niagara bridges, the Erie Canal, modern ordnance, and the Pacific Railway.

Among the great projects of the age are those for building canals, railways, tunnels, bridges and steamers. In canals, we have the project of one around the Falls of Niagara; a re-enlargement of the Erie for vessels of 1,000 tons; the Suez, nearly completed; one across the Alleghanies in Virginia; one through the Nicaragua Lake or Panama, and one from Huron to Ontario. In railways, we have the Pacific on the eve of completion; the Mont Cenis in rapid progress; one across the continent from Rio Janeiro begun, and many others of magnitude. Of bridges, we have those in progress across our great Western rivers; one proposed across the East River at New York of 1,600 feet clear span; two over the Hudson, above and below West Point; another across the Straits of Messina, covering the "Scylla and Charybdis with clear spans of 1,000 meters (two-thirds of a mile) each," and with piers of 700 feet high, half in and half out of the sea, and finally the modern "Pons Asinorum," a bridge project across the Straits of Dover, sixteen miles long, in clear spans of two miles each, with piers of a 1,000 feet depth in the water. This project is said to be favored by Napoleon. In tunnels we have that of Mont Cenis, eight miles, and of the Hoosac, five miles in length, both in rapid progress; one of wrought iron tubes at London, and another at Chicago, almost completed; tunnels proposed under the East and North Rivers at New York, under the Ganges at Calcutta, and under the Straits of Dover.

The New York and Brooklyn Bridge.—The Board of Consulting Engineers, consisting of Horatio Allen, W. J. McAlpine, J. Dutton Steele, Benjamin H. Latrobe, John Serrell, J. P. Kirkwood and J. W. Adams, have finished their conference, after having sat for three days, carefully examining the details of Mr. Roebling's plans. The result, says the "Times," is a full confirmation of them in their application to the proposed East River Bridge.

The span (1600 ft.) the Board considered entirely feasible. As to the piers; on the Brooklyn side there was a substratum of boulders which the current would not act upon or wash away; here a firm foundation would readily be obtained. But on the New York side the foundation would have to be laid upon a quicksand—substantially the same as that met with in excavating the Dry Dock, where not a stone was found in the whole excavation. It is however very hard, being a decomposed rock. The practical question was, will the scour of the river remove it and undermine the pier? A reference to old charts shows that the current has not encroached upon this shore. The pier might be carried down 107 ft. to solid rock, but the Board thought going deeper than the bed of the river, or say 70 ft., unnecessary. In case of future encroachments, a protection of rip-rap work could be put in. The sand will be loaded to 4 tons per square foot. Mr. McAlpine has found that this sand will safely sustain 10 lbs. per square foot. The masonry will be located on a mass of timber 165×100 ft.×20 ft. thick, bolted together so as not to allow settlement in detail. The durability of this timber, below the mud, is beyond question.

IRON AND STEEL NOTES.

Report of the American Iron and Steel Association.—The following abstract gives the more important features of this valuable report. It is published in full in the "Iron Age" of February 25.

The estimate of the production of pig iron for 1868, is 1,603,000 tons* as follows:

	Tons.
Anthracite	893,000
Raw coal and coke	340,000
Charcoal	370,000
Total	1,603,000

The product by States was as follows:

Anthracite.	
Pennsylvania	671,955
New York	160,681
Other States	60,364
Total	893,000
Raw Coal and Coke.	
Pennsylvania	194,000
Ohio	132,000
Other States	14,000
Total	340,000
Charcoal.	
New England	30,000
New York	27,400
Pennsylvania	59,600
Maryland	25,000
Ohio	86,000
Michigan	65,000
Other States	77,000
Total	370,000

The estimated value of the pig iron made in the United States last year, at the average price at the principal market for each kind of iron, was $,000,000.

The product of the forges and bloomeries in the country during the past two years was as follows:

	1867. Tons.	1868. Tons.
New England	8,462	7,500
New York	22,634	23,000
New Jersey	5,980	6,200
Pennsylvania	31,747	33,500
Other States	4,250	5,000
Total	73,073	75,200

Estimating the proportion of the above product for 1868, made direct from the ore, at one-half, or 37,600 tons, a proportion found by careful analyses for previous years to be correct, we find that the grand total production of iron from the one in 1868 was 1,640,600 tons.

The product of the rolling mills in 1868 is estimated at 1,105,000 tons, an increase of 63,000 tons over the production of the previous year. This increase was chiefly due to the larger production of rails amounting last year to 506,714 tons against 462,108 tons in 1867.

Of the total domestic production of pig and rolled and hammered iron, as previously stated, the following are the quantity and value shown with reference to the various kinds of products:

* Tons in all cases 2,000 lbs., unless specially stated otherwise.

	Quantity. Tons of 2000 lbs.	Average value.
Foundry pig	575,000	$22,425,000
Rails	506,714	34,384,148
Boiler and plate	111,462	15,047,370
Nails and spikes	149,000	16,390,000
Bar, rod, band, hoop, &c., axles and other rolled irou	337,824	35,048,850
Hammered iron	22,000	3,960,000
Total	1,702,000	$127,255,368

The total productiou of steel in 1868, including 8,500 tons made by the Bessemer process, is estimated at 30,000 tons. The capacity of our steel works is amply sufficient for all the requirements of the country. The excellence of American steel, and its adaptability for every purpose to which this material is applied, can no longer be questioned. No reasonable argument, therefore, can be advanced against such additional protection as this interest demands, and which will redound to the advantage of the consumer no less than the producer.

The following are the quantities and values of the various kinds of iron and steel, and manufactures thereof, imported into the United States during the last fiscal year, comprising the twelve months ending June 30, 1868:

	Quantity. Tons of 2000 lbs.	Value.
Pig iron	118,042	$1,810,482
Castings	....	32,674
Bar iron	66,383	2,906,231
Boiler plate	1,000	73,221
Band, hoop and scroll iron	15,878	672,264
Railroad iron	228,277	4,781,575
Sheet iron	15,821	1,187,644
Old scrap iron	72,908	1,283,269
Anchors, cables and chains of all kinds	4,306	315,183
Steel ingots, bars, sheets and wire	....	1,705,337
Manufacturing of iron and steel	....	8,728,955
Total	522,615	$23,496,835

Later figures than the above, however, are obtained by a reference to the reports of the British Board of Trade, that for the eleven months ending November 30th, 1868, having recently come to hand. By it we observe that during that period 93,073 tons of pig iron were exported to this country, a falling off, as compared with the corresponding months of 1867, of 34,910 tons, and exhibiting a slight increase as compared with the importations of 1866. Of bar, angle, bolt and rod 43,388 tons were shipped hither, against 46,171 tons in 1867 and 68,376 tons in 1866.

One of the most prominent features of the iron trade during the past year was the very heavy importation of railroad iron, amounting during the period above named to 278,035 tons, being 101,820 tons, or about 58 per cent over those of 1867, and 169,603 tons, or 156 per cent over those of 1866.

Supposing the quantity shipped to this country in the month of December to equal the average monthly shipments of the previous eleven months, the total quantity for the year would be 303,000 tons, or nearly forty per cent of the whole consumption of the country—a quantity largely exceeding the importations of any year in the history of the country, excepting 1853-54. The total quantity of iron of all kinds exported to this country from Great Britain during the eleven months being 438,305 tons, against 391,526 tons in 1867, and 313,957 tons in 1866. Of steel we imported 16,700 tons, a quantity somewhat less than during either of the two preceding years. Of the whole quantity of iron exported from Great Britain during the eleven months ending November 30th, 1868, about 24 per cent was shipped to this country. The percentage of each kind sent hither was as follows: of pig iron, 16 per cent; of bar, angle, bolt and rod, 14 per cent; of railroad iron, 46 per cent; of castings 11¼ per cent; of hoops, sheets and boiler plates, about 12 per cent; other wrought iron, 3 per cent; of steel, 53 per cent.

The value of iron and steel and manufactures thereof, exported from the United States during the last fiscal year was $9,114,740, as follows:

	Manufactured in United States.		Of Foreign Manufacture re-exported.	
	Quan'ty (cwt.)	Value.	Quan'ty (cwt.)	Value.
Pig iron	7,331	$14,022	....	....
Castings	5,112	18,815	....	$1,035
Bar iron	3,580	22,515	746	1,755
Boiler plate	....	....	42	291
Band, hoop and scroll iron	....	....	20	97
Railroad iron	189	1,304	14,000	20,097
Sheet iron	....	....	501	2,022
Anchors, cables & cable chains	....	....	31	8,046
Nails and spikes	53,972	371,317	....	....
Manufactures of iron and steel	....	8,521,437	....	131,987
		$8,949,410		$165,330

THE ELLERSHAUSEN PATENT.—The specification of Francis Ellershausen, of Ellershause, and Augustus E. Stayner, of Halifax, Nova Scotia, and Adolph Guzman, of New York, N. Y., Letters Patent No. 84,053, dated Nov. 77, 1868, for "Improvement in the Manufacture of Iron and Steel," is as follows:

"The nature of our invention relates to the production of iron in a new and useful condition, suitable for the general purposes of the manufacture of iron and steel, and combining the advantages of improved quality and diminished cost. To enable others skilled in the art to make use of our invention in the manufacture of iron and steel, we will proceed to describe our method of operation, and the results attained thereby.

"Our process consists substantially in mixing together cast iron and an oxide or oxides in such manner and in such proportions as to produce a solid (as distinguished from a fluid) mass, one, and either, of them being in a solid condition, and the other of them in a fluid state, by reason of heat applied to it previously to such mixing. We shall, in this specification, describe more particularly our process as applied to the treatment ef melted cast iron with solid oxide. We use cast iron, either taken directly from the blast furnace, or remelted; and for the oxidizing agent, iron ore, crushed or pulverized, may be most conveniently employed, although we do not desire to restrict ourselves to the use of any particular oxide. The mixing may be effected in any suitable receptacle or mould, of such dimensions as will give to the resultant mass the desired shape and size. An ingot mould in two pieces, united and held together by bands, will answer the purpose.

"In the bottom of this mould we first place a small quantity of iron ore, so that the mixing may commence as soon as the melted cast iron is introduced. We then pour into the mould a stream of liquid cast iron, and, simultaneously therewith, a stream of finely-crushed or powdered ore, keeping the flow of each as steady as possible, and stirring them constantly with a tool (preferably made of wood), so as to effect an intimate admixture. Care must be taken that there shall be fully enough ore for the operation. It will be found that on this admixture the liquid cast iron instantly becomes pasty, and then solid, so that as the materials are poured in and mingled, a solid (as distinguished from a fluid) mass is built up until the mould is full. Removing the full mould, and supplying a fresh one continuously, the operation is kept up until the whole of the cast iron has been operated on. On opening these moulds, by removing the rings and wedges by which the sections are held together, the mass formed therein is turned out. This mass is a loose, spongy ingot, from which the excess of ore which has not combined with the cast iron will shake out.

"To the material thus formed we have given the name of "pig bloom," if cast in a mould or other such receptacle, and preserved in the shape thus acquired; but if the ingot be broken up small, or if this material be formed in such a manner as to consist of smaller pieces, flakes, granules, plates or scraps, then we call it "pig scrap." This "pig bloom," and "pig scrap," will be found to be mechanical mixtures or conglomerates, consisting of particles or grains of cast iron, of ore, of perfectly converted wrought iron, and of still other particles in various intermediate conditions. But if there have been tolerable skill and care exercised in mixing, the mass will be converted into a condition so nearly akin to that of wrought iron that it will only need the judicious application of heat to resume and complete the chemical operations, which having been commenced in the process of mixing, were arrested by the cooling of the mass, in order to perfect the conversion of the cast iron and the ore into wrought iron, by the combination of the carbon of the carburet with the oxygen of the oxide. In fact, this part of the after treatment is conducted as if the result of the mixing of the ore with the cast iron were already pure wrought iron, because the heating which is given to it during the further working, will supply all the conditions required for actually producing wrought or malleable iron. It will also be found, in practice, that this "pig bloom" and "pig scrap" are capable of enduring, without damage, a very great exposure to heat, both in intensity and duration, and thus the impurities can be sweated out of the metal to an extent which is not possible by the old methods of iron metallurgy, or at least not without great expense.

"The making of the pig bloom, or pig scrap, in the manner described, affords a convenient and very efficient means of obtaining the good effects of such materials as are known to be beneficial, either as detergents or as alloys, in some of the operations of iron metallurgy (as in the crucible), but which have wholly or partially failed to assist in the blast furnace, the refinery, the bloomery, the puddling furnace, or the Bessemer converter. By combining such materials with the pulverized ore, they enter into intimate mechanical admixture with the mass of the pig bloom or pig scrap during the process of "mixing," before described, and being thus imprisoned in the mass, and subjected for a long time to a heat too great for them to endure as solids, they must either escape as fluids or gases, or else become chemically incorporated with the iron.

"Instead of "mixing" by pouring the streams of finely-crushed ore and of fluid cast iron simultaneously into a mould, the same result, substantially, may be reached by scattering the cast iron on the bed of ore, or by delivering it on a moving surface, upon which ore may be placed before or after the metal is deposited; or, indeed, a variety of methods may be devised whereby to bring the fluid cast iron and the solid ore into a contact sufficiently intimate to produce a conglomerate of the character hereinbefore described. The method of operation may also be varied by employing the oxide or oxides in a melted state, and the cast iron, granulated or otherwise finely divided, in a solid as distinguished from a fluid state, mixing them in such manner as to produce the conglomerate desired.

"Iron ore or oxide of iron, has been described as the oxidizing agent in our process, but we do not confine our invention to the use of that material, as other oxides may be used in combination with or in lieu of it. We are aware that the removing of the carbon of cast iron to a greater or less degree, by means of oxides, is not new, and that the mixture of solid oxides with fluid cast iron is performed in the puddling furnace, and in other operations ; but this is done under other conditions, and with different results. But the novelty of our process consists in mixing solid oxides into and among fluid cast iron, or of fluid oxides with solid cast iron, granulated or minutely subdivided, in such a manner and in such quantity as to produce a solid conglomerate of the two substances, and also in effecting this mixture, and producing the resulting pig bloom or pig scrap, without the application of other heat than that of the fused cast iron or oxide, as the case may be, thus dispensing with the use of a furnace for any part of the process of mixing after the melting of the cast iron or oxide, whichever of them is used in a fused condition.

"It will be found that the material thus produced may be used in like manner as any wrought-iron of similar shape, so that when raised to a welding heat, the pig bloom, manufactured as hereinbefore described, may be pressed, squeezed, hammered, rolled, or worked in any of the methods employed in the treatment of wrought iron, and with like results, excepting that the article of wrought iron produced by our process is superior in quality to that obtained in the ordinary way.

"What we claim as our invention, and desire to secure by Letters Patent, is—

"1. As a new article of manufacture, pig bloom, or pig scrap, being a conglomerate of cast iron, oxides, wrought iron, and particles of matter more or less nearly approaching one or other of those substances, produced by admixing, and bringing in contact with fluid cast iron, oxidizing substances in a solid state, in such a manner and in such quantity as to produce a solid condition of the mass.

"2. The mixing of cast iron with an oxidizing agent, one or other of which is rendered fluid by heat applied previously to such mixing.

"3. The production of wrought iron from cast iron, by mixing with the latter, while fluid, a sufficient amount of oxidizing material to produce a solid condition of the mass.

"4. The production of wrought iron from oxides of iron, by mixing the latter with molten cast iron to such an extent as to produce a solid conglomerate of the two.

"5. The employment of detersive agents and useful alloys, by mingling them, or either of them, with the oxides used in the process hereinbefore described, so that they shall become part of the conglomerate, and have such intimate contact and connection with the mass as to produce their proper chemical effects when it is afterwards subjected to the action of heat.

WELDING POWER.—A powder of the following composition, recently patented in Belgium, is said to be very useful for welding iron and steel together. It consists of one thousand parts of iron filings, five hundred parts of borax, fifty parts of balsam of copaiva or other resinous oil, with 75 parts of sal-ammoniac. These ingredients are well mixed together, heated and pulverized. The process of welding is much the same as usual. The surfaces to be welded are powdered with the composition, and then brought to a cherry-red heat, at which the powder melts, when the portions to be united are taken from the fire and joined. If the pieces to be welded are too large to be both introduced at the same time into the forge, one can be first heated with the welding powder to a cherry-red heat, and the others afterwards to a white heat, after which the welding may be effected. Another composition for the same object consists of fifteen parts of borax, two parts of sal-ammoniac and two parts of cyanide of potassium.—These constituents are dissolved in water, and the water itself afterwards evaporated at a low temperature.

a. Gray pig (63 Austrian cwt. 83 pounds) and blast furnace slag.

b. After the first period ; slag from the converter.

c. After the second period ; slag from the converter.

d. At end on turning down ; slag from the converter.

e. Finished product after addition of recarbonizer; slag from converter.

First period ceases when long bright flame appears.

Second period ceases, as long bright flame begins to grow darker.—*Kupelwieser, Oest. Zeitschr.*, 1867, *No.* 23.

CHROMIUM IN RAIL HEADS.—The London "Mining Journal" states that an improved metal for the manufacture of rails has been proposed, consisting of iron with an admixture of chrome ore. It has long been known that an alloy of about 40 per cent of iron and 60 per cent of chromium scratches glass almost as deeply as the diamond ; and Fremy has stated that an alloy of iron and chromium may be formed by heating in a blast furnace oxide of chromium and metallic iron ; it resembles cast iron, and scratches the hardest bodies, even hardened steel. Experiments, says this authority, are now being made at four of the largest rail mills in the United States, in order to test the value of an alloy of chrome ore and manganese, with the iron in the puddling furnace, for hardening rail heads, and with every prospect of a successful result.

TREATMENT OF STEEL PLATES.—The tensile strength of a steel plate, with proper degree of hardness, should give an ultimate strength of 33 to 35 tons per square inch. The denser the metal the more injurious the effect of punching. Steel plates of from 33 to 35 tons per square inch tensile strength, suffer more by punching than iron plates of from 20 to 22 tons per square inch, unless the steel plates are annealed after being punched.

Effect of Annealing the Plates.—The plates which had been punched were annealed, when the tensile strength of plate arose to 35.86 tons per square inch or to its original strength. The mean results obtained of experiments of strength of drilled plates riveted together, and of punched plates annealed and riveted together—plates off of same piece—gave for drilled plates 41.075 tons per square inch, and for the punched 41.24 tons per square inch, showing the punched plate when annealed to be equal to the drilled, if the latter is properly annealed. Plates were 5-16 inch thick, rivets 9-16 inch diameter, 1⅜ center to center, and double riveted.

Mr. Henry Sharp found the effect of drilling and punching steel plates to be as follows:

Number of test.	Thickness.	Area.	Breaking weight on lever.	Weight per square inch of section when drilled.	Weight per square inch of section when punched.
			tons. cwt.		
1 D....	5-16	0.5437	19 3	35.22	....
1 P....	5-16	0.55625	14 17	....	26.690
2 D....	5-16	0.55	20 10	37.27	....
2 P....	5-16	0.5625	13 5½	....	23.735
3 D....	5-16	0.5466	19 18	36.40	....
3 P....	5-16	0.5593	12 12½	....	22.570

Thus proving that punching deteriorated the tensile strength of steel plates, 5-16 inch thick, to the extent of from 26.4 to 37.8 per cent, as compared with drilling, or on an average of 33 per cent. On examining a section of steel or iron plates which has been punched, it will be found that the metal is more or less hard and brittle around the hole (the thicker and harder the plate, the greater the distance).

Effect of Taper Punching on Steel Plates.—Plate ½ inch thick, cut in two, one piece, punched with a punch ⅞ inch diameter, clearance being 1-16 inch hole in die. The other plate was punched with the same punch, but clearance in hole being 3-16, making a taper hole in the plate. The ultimate tensile strength of plates, unannealed after being punched, was for the taper hole 32.527 tons per square inch of net sectional area; for the straight hole 26 tons, being 25 per cent in favor of the taper-punched hole, the fracture of the taper-punched plates being more fibrous than the other.—*Am. Railway Times.*

THE PRODUCTION OF PIG-IRON.—The estimated production of pig-iron in the principal iron making countries of the old world is as follows:—The figures refer to the year 1865, which is the latest date for which complete returns are obtainable. In the United Kingdom 613 furnaces made 4,768,000 tons; France, 430 furnaces, made 1,195,000 tons; United States, 260 furnaces, 1,150,000 tons; Belgium, 52 furnaces, 450,000 tons; Russia, 300,000 tons; Austria, 314,000 tons; Sweden and Norway, 253 furnaces, made 246,000 tons; Italy, 37,500 tons; Spain, 60,000 tons.

HISTORY OF SMELTING WITH RAW BITUMINOUS COAL.—Early in the seventeenth century, mineral coal was introduced as a substitute for charcoal in the manufacture of iron; but, the first experiments with raw coal being unsuccessful, the process of coking or charking was discovered, and for a considerable time held secret. It was still believed, however, that coking not only added expense, but wasted fuel, as modern experiments have abundantly proved; and attempts to use raw coal were not wanting. In 1651, a special act of Parliament granted to one Jeremy Buck a patent "for making iron with stone-coal, pit-coal or sea-coal, *without charking.*" Of the success of his operations we know nothing, but presume they resulted in failure; at least, so far as bituminous coal was concerned. A review of this part of the subject will be found in Webster's reports of English patent cases, under the head of the celebrated Crane case. Crane's patent (Sept., 1836) was for the use of raw stone-coal; and it was disputed on the grounds, among others, that he used bituminous coal also, and that the whole was covered by the ancient patents of Buck and others. This plea opened up an extended historical argument.

All these early experiments were made with cold blast, and they were not sufficiently successful to effect a discontinuance of the use of coke. Indeed, it became a maxim among iron-masters that raw coal decreased the product of iron. But after the year 1831, when the use of the hot blast was made more general, the introduction of raw pit-coal began in earnest.

The foregoing is from the "American Journal of Mining." A letter from Col. Chas. Whittlesey to the same journal says: The first use of raw bituminous coal in a stack furnace is claimed to have occurred in 1845, on the waters of the Shenango, in western Pennsylvania. A furnace built the same year on the Mahoning, another branch of the Beaver, just over the State line, in Ohio, made iron with raw coal; and immediately other works sprang up on both rivers, all using the "block," or Brier Hill coal, and all making an article superior to any coke or anthracite iron in America or England.

THE CELLULAR STRUCTURE OF IRON.—It is stated that a crystalline malleable iron does not show prisms is its fracture, but simply a number of faces of planes crossing the cells at right angles, cutting them off short. The process of rolling iron into plates or sheets does not obliterate these cells, but merely modifies them, as they widen out under the pressure; the thin partitions become laminated, and on the regularity of this lamination the quality of the plate very much depends. The cell system of copper is more perfect than that of iron, a result of the pouring of the copper into molds, but the cells are afterwards altered by the pressure in rolling, &c., but never destroyed. If it were possible to make a section one-millionth part of an inch in thickness these cells would be seen.

THE WILSON FURNACE.—The reported production of E. B. Wilson's puddling furnace is sixteen hundredweight of coal to the ton of puddled bars, running night and day. This shows a great saving over what has been used as a general thing in England, or wherever coal is cheap; but it is not so economical as a double puddling furnace built in the Cold Brook Iron Works, St. John, N. B., by Mr. John Wilson, an English furnace builder. This furnace made 42 tons ten hundredweight of six-inch bars (Scotch pig iron) with 27 tons of coal, half Cumberland and half Pictou, equal to twelve hundredweight and three-quarters to the ton of 2,240 pounds.—*Cor. Scientific American.*

ORDNANCE AND NAVAL NOTES.

Breech-loading Small Arms.—On this subject the "Engineer" says:

The great question of breech-loaders for military purposes seems to have reached its most important point, and already seems to lose a large share of interest accorded to it by the general public. The year 1867 was one of great change; last year was rather one of routine. The Small Arms Committee, at Woolwich, after having, early in the year, adjudicated the premium to Mr. Henry, set about their task of choosing a rifle for permanent use, either by availing themselves of the complete design of some candidate for Government remuneration, or by adapting the chief features of several into one perfect weapon. To perform their task efficiently they would necessarily have to institute a long course of experiments of great value in the aggregate, but of little general interest. Thus their time has been occupied for the year, and we believe we are correct in stating that in all probability their report will be published this month.

The report referred to has now been published. The "Army and Navy Gazette" thus comments upon it:

We understand that at length the report of the select committee on breech-loading firearms has been sent in, and it appears, as stated by us several weeks ago, the arm selected is a combination of the Martini action, modified by the committee themselves, and the Henry barrel. Without ourselves impugning this decision, we must, at the same time, say that, among very competent men, there is great doubt that such a combination will recommend itself either to military men, or those conversant with the adaptation of mechanical principles. We may briefly state a few of the objections to the Martini action. 1. A spiral spring has never been found to work with certainty in any arm yet tried. From its nature it is weakest when the blow is given to the cap; and the more the spring is expanded in the act of striking, the less its force, so that the impact partakes more of the nature of a sharp push than the actual blow necessary to ignite the fulminate in a cup. 2. There is always a certain amount of gas which combines the wax used as lubrication for the ball, and also round the cap itself. It is evident a portion of this is continually finding its way into the interior of the block through the opening in which the piston works, as well as at the slot, where the spiral spring acts on the trigger. This will necessarily tend to clog the spring and weaken its already uncertain action. 3. In intense cold—such as is found in Canada and other parts of the world, where the thermometer is frequently from 50 to 60 degrees below freezing point, and at other times from 90 degrees to 100 degrees above it—the condition of the steel in the spring would be so altered that it would be very liable to snap, and be rendered useless at the very time it might be required to act; and however easy it may appear to replace the spring in a workshop, it is not so in an exposed cold place, amidst falling snow, or in the face of an enemy. 4. The front part of the block is obliged to be made with convex face, and in consequence is tangent, and not parallel to the disc of the cartridge, therefore does not back it up as it should do. The result is that the arm is dangerous from the unsupported cartridges bursting, and the pieces of brass foil, of which the cartridge cases are made, being blown into the face of the soldier firing the arm. We understand that this has been endeavored to be overcome, by adding a spring to the block to force the face of it up to the cartridge, but this, it is held, would only add to the risk of clogging, and eventually render the arm useless until taken to pieces and cleaned by an armorer. 5. In loading the arm, should the trigger by any chance be caught in the dress or accoutrements of the soldier, it would not act. When the block closed the arm would, in all probability, be fired, as the whole force of the spring would be in the cap instead of being held back. 6. The breech-block works on a small pin, and, should this pin be too soft, it would soon wear loose and render the block still more dangerous, by causing it not to support the disc of the cartridge even at the point already named. If too hard, it would be liable to snap under the influences of the weather; the blows given by the constant firing would also alter the nature of the iron, by causing it to return to its crystalline state. 7. Extracting the empty cartridge case is effected in this arm by giving a smart pull forward to the trigger-guard when opening the breech. If at any time the pull is not sharp enough, the cartridge case sticks half way, and cannot be got out of the chamber without using the ramrod, and, on the other hand, should the pull be too hard, the empty case is apt to be sent into the face of the soldier firing, or that of his rear rank man. 8. The stock of this rifle is in two parts, which must weaken and unfit it for the rough usage of actual service. On the whole, we are assured that this arm is no improvement on the Peabody rifle, which has already been rejected. Nay, inasmuch as it has the manifest disadvantages of the spiral spring action, the latter weapon is held to be superior, and it is maintained that a rifle, on a bolt principle, will be found, for a military weapon, more safe, simple and effective, conclusions which have been arrived at by two of the greatest and most scientific nations on the continent—France and Prussia. There can be no doubt that the Henry barrel is a most accurate one, but whether it is well adapted for the rough usage of a military arm is a moot point.

In Prussia, says the "Journal Official," the results of a comparative trial which took place in the School of Musketry, at Spandau, amongst the breech-loaders adopted by the different armies, were, according to the official report, the following: The Prussian needle gun can fire 12 shots a minute, the Chassepot 11, the Snider 10, the Remington (Denmark) 14, the Peabody (Switzerland) 13, the Wœnzi (Austria) 10, the Werndi (same State) 12, and the Winchester repeating rifle (United States) 19.

In France the failure of the Chassepot and needle guns is announced. A correspondent of the "Army and Navy Gazette" says: The French and the Prussian Governments, after repeated experiments, carried on at a great cost, have arrived at this conclusion, and admit the fact—that the Chassepot and the needle gun (both on the spiral-spring principle) are useless for the central-fire cartridges, which they have now determined to adopt. Another authority informs us that the French Government have ceased to manufacture the Chassepot, and taken to the Remington instead. The Remington—the only rifle, by the way, which Prussian military men think superior to the Zündnadel—has been likewise introduced into the Danish and Swedish services.

American Rifles Abroad.—During the past year, Messrs. Remington & Sons, of Ilion, N. Y., have made 86,000 of the "Remington" breech-loaders of various styles, to fill foreign orders, and are now engaged in the manufacture of 40,000 "Berdan" breech-blocks for a Spanish contractor, to be used for the conversion of old muzzle-loaders, or to be applied to new guns, in Spain. We learn by a letter from Paris, written by one who ought to know, that orders are expected shortly from various European governments for about a million and a half of breech-loaders, and five hundred millions of cartridges. The greater portion of these orders will doubtless come to this country, and Messrs. Remington will undoubtedly receive a large share.

War Rockets.—At a recent meeting of the Manchester Literary and Philosophical Society, a paper was read on war rockets by Mr. J. Nasmyth, C. E. Mr. Nasmyth observed: It may be well to allude to the means that have been employed in the endeavor to secure to war rockets rifle action or precision of flight. These consist in placing the rocket in a V-shaped trough, by which the direction and inclination of the rocket is suitably secured previous to commencing its flight, and so far holding the rocket fair in the direction of the object aimed at. Besides this, an endeavor is made to give the rocket axial rotation during its flight by causing the propulsive gases, while issuing at the rear of the rocket, to rush through skew holes. This latter arrangement does, to a certain extent, give to the rocket axial rotation. But, as axial rotation given by such means does not come into effective operation until the rocket has proceeded a long way on its course, it comes into action too late to have any influence in securing precision of flight. In order, then, to effect our object, I place the rocket inside a tube, into which it slides freely; to this tube, which serves to secure the aim of the rocket, I give, by mechanical means, an axial rotation of some thousands of revolutions per minute, which is transmitted to the rocket then resting within it. The rocket, while thus revolving on its axis at the high velocity above named, is then fired, and so rushes forth from its guide tube impressed with all the conditions of a perfect rifle projectile, and, as such, with every condition present that can secure its reaching the object aimed at. The mechanical means and arrangements by which I propose to effect the object in question consist of a suitable iron stand, supporting the rocket and its guide tube, the latter resting on loose friction wheels, which, while preserving with the utmost exactness the direction of the axis of the guide tube and rocket, permits the guide tube and rocket to revolve on its axis with all due facility. The requisite amount of axial rotation is conveyed to the guide tube, and thence to the rocket resting within it, by means of a powerful clock spring transmitting its rotation to the rocket through a train of wheels. Previous to firing the rocket the second of this train of wheels is locked by a catch or trigger; the string is then wound up, and the aim and elevation of the rocket adjusted. The match of the rocket is then lighted, and in order to secure energetic combustion of the rocket ere it is allowed to rush forth on its course, the rocket is held in check by three slight springs within the guide tube at the rear of the rocket, by means of which it is not permitted to rush forth until the proper energy of discharge of propulsive gases has been acquired. As soon as this is the case the rocket frees itself and then rushes forth impressed with and possessing every condition of a true rifle projectile, combined with all those important properties which rockets possess as implements of war.

Failure of Large Breech-Loading Cannon.*—Says the "Army and Navy Gazette": There are serious rumors abroad respecting the new marine artillery. Somewhat more than a year ago France arrived at a different conclusion to that of most other nations, and "went in" for large breechloaders, with which she immediately armed her fleet. The breech would be difficult of description; suffice it to say that it is unlocked and removed on a movable platform. In a great many instances this apparatus has broken down during practice, and several guns have been altogether condemned. The strain of heavy charges has proved too severe a test on the mechanism, which gets out of order, and renders the piece difficult to be loaded or entirely useless.

* See "Ordnance and Armor," pages 580 and 608, for description of these guns, and predicted failure of large breechloaders.

As to the Armstrong guns, the "Army and Navy Journal" says: The English War Department, after spending millions of money on the Armstrong breechloading-wrought-iron-coil-rifled gun, knighting its inventor, and growing almost wild over their toy, have now finally abandoned the last vestige of the Armstrong system. It may, therefore, be stowed away among the relics of the past. Some patriotic loyal Americans, it will be remembered, took the Armstrong infection, and subscribed a handsome sum of money to present a battery of these guns to us, in the early part of the war. They seemed to be grieved that we had to trust to our simple smoothbore muzzle-loaders, when such a triumph of artillery-making was in existence. And some of our (present) English friends and admirals subscribed even more liberally to furnish the rebels with a lot of these guns, and others got into the Southern forts in various ways, so that they used to turn up every now and then when we took a Confederate stronghold. And yet, alas! their course is even now run! The British War Office has issued an order, intimating its purpose to withdraw all the breech-loading rifled guns and substitute muzzle-loaders. We learn from "Engineering" that the Ordnance Select Committee, at the request of the superintendent of the Royal Gun Factories, had been called upon by the War Department to decide on the peculiar construction upon which the 12-pounder, 9-pounder and 7-pounder rifled muzzle-loading guns, estimated for 1868–'69, are to be manufactured. They replied, subject to the Secretary of State for War's approval, that the 12-pounder and 9-pounder guns should be made in accordance with the tracings already approved to guide the manufacture of the experimental 12-pounder muzzle-loading gun, recently tried at Shoeburyness, with a view to the determination of the elements of rifling for these guns, as well as of the 12-pounder and 9-pounder experimental guns ordered for trial on board Her Majesty's ship Excellent.

European Iron-Clad Fleets.—The North German iron-clad fleet consists of five ships, viz: two cupola ships with 3 guns, two ships mounting 16 and one mounting 24 guns. All the guns are rifled breech-loaders of Prussian construction. Four of the ships are of iron. The King William, the largest of the five, has a tonnage of 5,939 and engines of 1,150 nominal horse power. The thickness of the plates used for these vessels varies from 4½ to 8 inches.

"Les Luttes de l'Autriche en 1866," lately published, states that the Austrian sea-going iron-clad fleet consists of two frigates of the first class, three of the second, and two of the third. They carry an aggregate of 213 guns and 2,592 men. There is also an iron-clad battery of position, with an armament of sixteen guns and a crew of 229 men. The same publication gives the strength of the Italian iron-clad fleet at four frigates of 36 guns, four of 26, and three of 22 guns each, one ram with 2 guns, two corvettes of 20 guns, two sloops of 4 guns, and two batteries of 12 guns each—in all eighteen vessels, with an armament of 388 guns and an equipment of 7,358 men.

Krupp's 11-inch Gun.—The 11-inch steel gun made by Krupp for the Russian Government, is the largest breech-loader that has ever stood a practical test. The gun weighs 26 tons, and has no preponderance. The rifling is 36 grooves of 770 and 788 in. pitch, 0.135 in. deep, and 0.64 (muzzle) to 0.79 (chamber) wide. The projectile weighs 495 lb.; the charge 82½ lb., giving an initial velocity of 1,360 ft. per second. The number of test rounds was 400, with substantially the above charges. The Prussian and the Belgian Governments have lately ordered a large number of Krupp's 9-inch guns.

THE GOVERNMENT AND INVENTORS.—The following circular, issued by the British Government, will be specially interesting in view of the current investigations, reports and general excitement on the subject among inventors interested in improving war material:

"In consequence of the numerous claims for compensation for loss of time and for expenses incurred by private individuals in working out inventions of various kinds, as well as for rewards in consequence of such inventions, the Secretary of State considers it necessary to make known the following regulations:

"1. Persons who desire to submit any invention for consideration should do so by letter, addressed to the Under Secretary of State. The letter should describe the invention, and state whether the person who offers it for consideration desires to make any claim to remuneration in connection with it. In the absence of such a statement it will be assumed that no such remuneration is expected.

"2. Expenses incurred before the submission of an invention will not be considered to give a claim for repayment. No liability on behalf of the public will be recognized on account of loss of time, or expenses incurred in connection with an invention after such submission, unless authority for such expenses has been previously given by letter signed by one of the Under Secretaries of State; and the liability will be strictly confined to the limits of expenditure authorized in such letter.

"3. All claims for reward will be examined by a council to be held at the War Office, and if any reward be recommended by the council and approved by the Secretary of State, the sum will, with the concurrence of the Treasury, be included in the estimates, together with the report of the council; but it will not be regarded as due or be paid to the claimant until after the vote is passed by the House of Commons.

"4. No claim for reward will be held to be established unless the invention has been adopted into the service or substantial benefit to the public has resulted from it."

THE ARMIES OF EUROPE.—The following statement of the nominal strength of the armies of Continental Europe was not long since given by Baron Kuhn, in the Austro-Hungarian Parliament:

France.	
Army	800,000
Mobile National Guard....	550,000
Total.....	1,350,000

North German Bund.	
Standing army	843,394
Landwehr	185,552
Total.....	1,028,946

South Germany.	
Standing army	156,760
Landwehr	43,411
Total.....	200,171

North and South Germany together.	
Total.........	1,229,117

Austro-Hungarian Monarchy.	
Regular forces, inclu'g navy & reserves ..	800,000
Border troops .	53,000
Landwehr	200,000
Total.....	1,053,000

Russia.	
Field army, including army of the Caucasus.......	827,350
Local forces ..	410,427
Irregulars	229,223
Total.....	1,467,000

Italy.	
Army.........	348,461
Mobile National Guard, including Venetia	132,300
Total.....	480,461

THE MONCRIEFF SYSTEM.—We are glad to be able to announce that the Moncrieff contrivance for mounting heavy artillery has been definitively accepted by the Government. Hitherto, as our readers are aware, a $6\frac{1}{2}$-ton gun is the heaviest which has been mounted on this system; but if it is to be really useful, it will have to be employed with much heavier ordnance, and steps are to be taken at once to apply it to a 12-ton gun, as a step towards its further development. Captain Moncrieff has been treated with a prompt liberality. He is to receive, first, a sum of money sufficient to cover the cost of his models and his preliminary expenses. Secondly, he is to receive payment for the time that he has devoted exclusively to the public service (about two years, we believe), at the rate of £1,000 per annum, which rate of pay is to continue so long as Captain Moncrieff is engaged in rendering assistance in making and completing designs for the application of his system, and in superintending the construction of his carriages. Thirdly, he is to receive £15,000 as a reward for the invention, and for the use which may be made of it in Her Majesty's service, either afloat or ashore, in any modification or combination. Captain Moncrieff on his part is required to undertake to communicate fully and unreservedly all improvements which he may deem practicable; in fact, to give the benefit of his knowledge of this particular subject to the country. Of the sum of £15,000, £10,000 is to be paid at once, the remaining £5,000 when the inventor ceases to draw his salary of £1,000 a year. These terms, we say, are liberal, and no doubt they will so be generally regarded; but they are not excessive.—*Engineering.*

THE PALMER SHELL.—A series of trials with a new shell, designed by Mr. Palmer, have recently been commenced at Shoeburyness. The shell is formed with a solid head and a base plate, the intermediate body being built up of a series of rings with serrated edge, which fit closely one upon the other, and together form a short cylinder; a through bolt, tapped at each end, passes through the solid head and the body of the shell, and is bolted to the base, holding the whole together. At the upper end, channels are cut in this bolt, to receive the fuze and communicate the fire to the bursting charge. The upper end of the through bolt is not flush with the point of the shell, but is recessed sufficiently to allow of the introduction of the fuze, which therefore abuts upon the top of the bolt, and cannot be driven into the shell at the moment of impact, as happens at present in the service shell. Two forms of shells were supplied by Mr. Palmer for the first trials at Shoeburyness, the one having a conical, the other a hemispherical head. The bursting charge was introduced through a hole in the bottom plate, which was afterwards closed with a gun-metal plug; the shells were fired from a 64-pounder rifled muzzle-loading gun, with the service charge of 8 lb.

TEN-INCH ARMOR PLATES.—The 10-inch rolled armor plates for protecting the four 22-ton 600-pounders which will be mounted in the two turrets of the iron-clad armored turret ship Monarch, 7,510 tons, 1,100 horse power, have arrived at Chatham dockyard from Sheffield. The plates are the largest ever yet operated upon at Chatham dockyard, each being 19 ft. in length, and weighing rather more than 12 tons. The process of bending the plates has been carried out by means of Westwood and Baillie's powerful hydraulic plate-bending machines, each plate having been bent to the arc of the circle it is to occupy on the turrets without giving signs of the slightest flaw. The plates will lose about two tons each while in the factory, the space occupied by the turret gun ports being cut from each.

RAILWAY NOTES.

Notes on Cheap Railways.—The following observations, by M. Desmousseaux de Gioré, C. E., on this important subject, from the "Correspondant," will be of interest to many of our readers at the present moment:

A railway is determined by two elements, which are, to a certain extent, independent of each other, namely, the weight of rails and the gauge: the weight of rails determines that of the engines; the gauge determines (according to the usual speed of traffic) the radius of the curves. On the principal lines of England and the Continent, the rails weigh about 36 kilogrammes per meter ($72\frac{1}{2}$ lb. per yard), and bear engines weighing 12 to 13 tons per axle; the gauge is about 1.50 meters (nearly 5 ft.), the radius of the curves being limited consequently to 500 meters (25 chains) on lines of rapid trafic, and to 300 meters (330 yards) on branch lines. The average cost of these lines is from 200,000 to 500,000 francs per kilometer, *i. e.*:

	Per kilometer.	Per mile.
For the great English lines,	545,000 fr.	£35,000
" French	305,686	19,647
" Belgian	230,000	15,000

In authorizing the construction of local interest lines, the French Administration has usually stipulated (at least as a condition of the State or department subsidy) that the great lines should have power to run their carriages over them; this clause has made the gauge of 1.50 m. compulsory, together with a minimum weight of rail of 18 kilos. per meter ($36\frac{1}{2}$ lb. per yard); but it soon became necessary to raise this weight to 25 kilos. ($50\frac{1}{2}$ lb. per yard) in order to adopt sufficiently powerful engines. The gauge being 1.50 m., it was necessary to limit the radius of curves to 300 meters, so as to avoid an excessive resistance. To such conditions, the cost per kilometer is usually between 100,000 and 110,000 francs (£6,440 per mile). It can be reduced, but not with safety, to 60,000 francs (£3,900 per mile). A frequent cause of excessive prices is the common prejudice against gradients, to reduce which expensive viaducts and works are incurred. But if engineers adopt steep gradients, and especially if they avoid joining the new lines with the old ones, they can reduce indefinitely the gauge and width of rails, and, consequently, the price per kilometer. For instance:

1. The railway from Breclthal (Prussia): gauge, 0.78 meters ($2\frac{1}{2}$ ft.); weight of rails, $10\frac{1}{2}$ kilos. per meter (21 lb. per yard); cost, 23,000 francs, including rolling stock; the radius of curves is 38 meters ($41\frac{1}{2}$ yards); the line is 20 kilometers ($12\frac{1}{2}$ miles) long; it occupies one side of the carriage road; the engines, loaded, and ready to start, 12 tons, with 6 wheels.

2. Railway of the sugar works (beetroot) at Tavaux-Pontséricourt, in the department of Aisne: two railways; gauge, 1 meter (3 ft. $3\frac{3}{8}$ in.); width of rail, 13 kilos. per meter ($26\frac{1}{4}$ lb. per yard); cost, 28,000 francs (£1,800 per mile), including all stock. Engines on four wheels weigh $7\frac{1}{2}$ tons, loaded; radius of curves, 30 and 40 meters (33 and 44 yards). The ground is very rugged; the section shows frequent gradients of 0.015 to 0.025, then long gradients of 0.050 and 0.060, and even one of 0.075; on a length of 300 meters (330 yards.) Messrs. Molinos and Prosnier, engineers of the line, and managers of the sugar works, might, but for the exceptional natural difficulties, have reduced the cost to 20,000 francs (£1,300 per mile). These lines are made on the side (*accotement*) of the vicinal roads. The legal formalities by which the necessary powers were obtained were very simple, the "communes" consenting to abandon to the company a strip of land of 1 meter in width on the side of the road, with power to add 1 meter to it. The two railways of Tavaux-Pontséricourt traverse two villages, without causing any inconvenience to the inhabitants. The legal formalities and construction were all completed for the greater part of the lines in six months.

The following cheap railways are described by Messrs. Flachat and Goschler, in their Exhibition reports:

3. Four Norwegian railways: gauge, 1.07 meters (3 ft. 6 in.); weight of rail, 20 to 22 kilos. (43 to 48 lb. per yard); weight of engines (four wheels) loaded, 17 tons; total length of lines, 300 kilometers (186 miles.)

4. Commentry and Monttucon line: gauge, 1 meter (3 ft. $3\frac{3}{8}$ in).

5. Antwerp and Gand line: gauge, 1.15 meters (3 ft. $9\frac{1}{4}$ in.). 16 trains run daily on this line at a speed of from 40 to 60 kilometers (25 to 36 miles per hour). In 1865, nearly 500,000 passengers were conveyed on it.

6. Mondalazac Railway, established by the Orleans Railway Company: gauge, 0.75 (2 ft. 5 in.); weight of rail, $16\frac{1}{2}$ kilos. per meter ($33\frac{1}{4}$ lb. per yard); radius of curves, 40 meters (44 yards); weight of engines (four wheels), loaded, 9 tons.

7. Festiniog Railway, near Caernarvon: gauge, 0.61; weight of rail, 15 kilos.; length, 21 kilometers; gradients, 0.0167; radius of curves, 40 meters; weight of engines, loaded, $7\frac{1}{2}$ tons; speed of trains, 16 kilometers per hour. From 1862 to 1863, this line was worked by horses. By using locomotive engines, the working expenses have been reduced 22 per cent.

This line is completely described in the "Engineer" journal.

8. Line built by Mr. Ramsbottom, C. E., at the Crewe Works of the North Western Railway: gauge, 0.46 meters (1 ft. 7 in.); radius of curves, 4 meters ($4\frac{1}{2}$ yards); speed of train, 10 kilometers ($6\frac{1}{4}$ miles per hour); weight of engines (4 wheels), $1\frac{1}{2}$ ton. A similar railway on the *accotement* of a road would certainly not cost 15,000 francs per kilometer (£1,000 per mile).

9. The Mont Cenis Railway, with central rail, invented formerly by M. Séguier, and re-invented by Mr. Fell: gauge, 1.10 meters ($3\frac{1}{2}$ ft.); gradients, 0.045.

Among the broad gauge* railways, the cheapest are:

1. In Scotland, according to a Swiss engineer, Mr. Bergeron, ten cheap railways, length from 10 to 30 kilometers (6 to 18 miles); cost, including rolling stock, from 73,000 to 145,000 francs (£4,700 to £9,400 per mile). Established ten years ago; others have probably been added since.

2. Vitré and Fougères Railway, 36 kilometers ($22\frac{1}{2}$ miles) in length; constructed by M. Debauge, at the rate of 67,500 francs (£4,400 per mile), including all stock. If the directors had not had the

* There is only one gauge in the original railway system of France, namely, 1.44 meters (5 ft. $8\frac{1}{2}$ in.). This is called broad as compared to those described above, but is very different from what we call the broad gauge.

unfortunate idea of connecting this line with the "Ouest," they could have reduced the expenditure to 56,000 francs (£3,600) per mile.

The above instances are sufficient to show the absurdity of constructing, as French companies are doing now, unproductive railways at a cost of 400,000 francs per kilometer (£26,750 per mile).—*Railway News.*

Extent of our Railways — Consumption of Rails.—The following statistics are from the late able and interesting report of Henry McAllister, Jr., Secretary of the American Iron and Steel Association:

	Miles.
The number of miles of railroad (including second track, sidings, &c.) in use December 31st, 1868	52,550
Total increase for 10 years ending December 31st, 1868	16,536
Total increase for last 5 years	9,448
Average annual increase for the last 10 years	1,654
Average number of miles in use for 10 years ending December 31st, 1868	43,123

	Tons.
Iron required in laying 43,123 miles averaged at 90 tons per mile, 3,781,070 tons, which at 6⅞ per cent for average annual wear, gives iron required for renewal of track	259,948
Iron required for last 10 years for renewing track	2,599,480
Iron required for last 10 years for new track, 16,536 miles, averaged at 96 tons per mile	1,587,456
Total consumption of railroad iron for last 10 years	4,186,936
Iron rails imported for 10 years ending June 30, 1868	1,015,685
Quantity of rails manufactured in the United States during the last 10 years	3,171,251
Average quantity of rails imported per annum for last 10 years	101,568
Average domestic production per annum for last 10 years	317,125
Total average annual consumption for last 10 years. (About 62 per cent of the consumption of rails is required for renewals and 38 per cent for new track)	318,693
Importation of rails for year ending June 30th, 1868	228,277
Production of American mills for year ending December 31st, 1868	506,714
Increase of importations on average of 10 years	126,709
Increase of domestic production on average of 10 years	189,589
Net increase of consumption in 1868, upon annual average of last 10 years	316,298

It seems to be the impression, particularly among those whose observations do not extend beyond our great trunk lines, that the percentage of rails worn out during each year is much greater than that given above, but this cannot be the case unless all the estimates that have been made of the number of miles of railroad in the country have been greatly exaggerated. It must be remembered that whilst many of the rails on main lines near our great railroad centers are worn out in a single year, there are thousands of miles of track in the Southern States and in the thinly settled portions of other sections that last over twenty years. In England, the actual waste of iron rails by grinding, oxidation and loss, is said to amount to 20,000 tons a year, while about 250,000 tons require to be taken up and re-rolled. As the number of miles of road there, including second track and sidings, may be safely put down at 23,000, it follows that the average wear and tear of track amounts to 10.36 per cent per annum. Even in that country, where the destruction of track is so much greater than here, we are told that on some lines of light traffic, rails frequently last twenty years, while on lines near London which are under constant and heavy work, many miles of track require re-laying in less than twelve months.

British Railway Accidents.—In the year 1867 the railway companies of the United Kingdom paid £347,379 as compensation for personal injury, 209 persons having been killed, and 795 persons injured; nineteen passengers were killed, and 689 injured from causes beyond their control, and seventeen were killed and eight injured through their own misconduct or want of caution. Fifteen servants of railway companies or of contractors were killed, and 62 injured from causes beyond their control, and 90 were killed and 28 injured through their own misconduct or want of caution; ten persons were killed and two injured at level crossings; 57 trespassers were killed (six were suicides), and five injured. In the six years 1862–67 the railway companies paid £1,460,568 as compensation for personal injury done upon the railroads. In those six years 1,268 persons were killed upon the railways, and 4,426 injured; and among them were 112 passengers killed and 3,897 injured without any fault of their own, and 97 passengers killed and 29 injured owing to their own misconduct or want of caution The risk of life in railway traveling may be expressed thus: In the year 1867 one in about eight and a half million passengers was killed—namely, one in every sixteen millions from causes beyond his control, and one in about every eighteen millions from his own misconduct or want of caution.

New Iron Railway Bridge in Italy.—MM Cail & Co. have contracted with the Upper Italy Railway Company for an iron girder bridge to be erected over the Po at Pontelagoscuro. The length of the bridge will be about 1,400 ft., with four spans of 247 ft. and two of 206 ft. It will be a single line, and supported by two lateral double lattice continuous girders, distant 15 ft. The piers and abutments will be sunk with iron caissons and compressed air. The weight of the superstructure will be 1,267 tons, and the price £24 per ton. Besides that, the price of each pier will be £4,720. There have been for this contract six competitors, all very large firms of France or Belgium.

Economy of Railway Transportation.—On a common road, wheat would consume its own value if carried 350 miles, while by rail it can be carried 3,000 miles at a profit. Railroads multiply by 10 the distance from any grain market at which its wheat may be raised. The same remarks apply to other productions, such as ores.

Railways in Canada.—After some years of inaction the minds of the Canadian people seem to be again undergoing agitation on the subject of railways. We have several times in this journal made reference to the proposed narrow-gauge lines, and it appears that the promoters of them are working energetically to accomplish their ends; it is sincerely to be hoped, however, that before they come to actual construction they will reconsider the whole matter and determine to adopt the gauge of the country. A Canadian correspondent writes to us concerning these lines as follows:

"One thing they are doing, however, which cannot fail to produce a healthy feeling in the public mind, and to convince people here that if they wish for railway accommodation, themselves must lead the way. The promoters of the narrow-gauge lines are thoroughly canvassing every municipality interested for aid by bonuses to their several projects, and they are meeting with a large measure of success. The principles they are endeavoring to instil into the minds of the people may be briefly stated as under: That the lines will be a vast and immediate service to the districts they pass through and will accommodate; that the country is too sparsely populated to warrant the assumption that they would pay in themselves as a commercial investment; that to insure the construction, at least one-third of their estimated cost should be a free gift from the municipalities; that they believe and hope one-third more can be raised in stock, and, if so, that no difficulty should be experienced in raising the remaining one-third, in the debenture bonds of the road. Whether they are right in the last impression or not, it is not for me to say, as they have issued no prospectus nor given the outside public any means of judging what their prospects of traffic are.

"The Port Whitby and Port Perry Railway scheme was chartered at the same time as the two narrow-gauge railway projects, but the directors of this line have wisely eschewed the error of departing from the established gauge of the country. This road will be about twenty miles in length, its southern terminus in Port Whitby on Lake Ontario, and its northern terminus in Port Perry on Lake Scugog; it lies wholly within the county of Ontario, and for its entire length will be of the utmost value as a thoroughfare for that important county, and will realize a considerable amount in local and thorough traffic. But the staple trade of the line will consist in its traffic in sawn lumber, Lake Scugog, with Port Perry at its head, forming a collecting depot for a vast chain of inland lakes and rivers, whose shores abound in pine timber of a very valuable description. It is estimated that this vast lumbering district will for a long series of years yield large supplies of timber for the American markets, while the lakes and rivers alluded to afford water conveyance of the cheapest character to the northern terminus of this railway, while the railway itself affords the shortest "portage" to Lake Ontario f om whence the lumber will be distributed to the various markets in the United States. Already the directors have had written contracts offered them for freight amounting to forty millions of feet, board measure, of sawn lumber annually; while in the prospect of the road being built numerous saw-mills are now being erected, depending on this railway as an outlet for their manufactures."—*Engineering.*

Cost of British Railways.—Ten years ago, the Brighton Company's system was 180 miles in length, and had cost eight and one-third millions, or £46,250 per mile. Since then the mileage has doubled, being now 365 miles, and the capital has more than doubled, standing now at about twenty millions. No less that five and a half millions of capital were raised between 1862 and 1866, and this without increasing the gross receipts by more than about 15 per cent. Yet as long ago as 1854, with but £7,690,000 of capital raised, the gross receipts were upwards of £685,000, whereas in 1866, with twice and half the capital, they had increased to but £1,190,000, or by but little more than one-half. The whole system of 365 miles has now cost nearly £55,000 per mile, on the average of the main line, extensions, and branches.

It will not be long after the meeting of Parliament, before it will be shown beyond disproof—although, of course, not beyond dispute—that a new main line can be made to Brighton at a total cost, including land (the latter alone taken at about £14,000 per mile), of only £35,000 per mile, and it can be as clearly shown that the first class fare between London and Brighton need not—and if an Act be obtained fixing the fare shall not—exceed 6*s.* for the 50 miles.—*Engineering.*

Business of the World's Railways.—According to the calculations made by the Government Statistical Office at Berlin, the number of passengers conveyed daily by the railways of the world amounts to three millions, and the quantity of goods to twenty-seven millions of centners, or a million and a half of tons. Also 58,000 telegrams are forwarded, and four millions of letters delivered every day. The daily gross receipts of the railways are 8,000,000 florins; they possess 40,000 locomotives, 1,200,000 carriages and vans, and give regular employment to a million persons. The aggregate length of the telegraph wires would, if united, reach to the moon and back again.

English Railway Carriages.—The long eight-wheel carriages of the Metropolitan railway weigh, with their gas apparatus, about sixteen tons, empty. The first class carriages seat 56 passengers; the third class, 80. A few four-wheel carriages are now being made of half the length and capacity, to weigh about seven tons each.—There will be a moderate saving of weight, but at the sacrifice, perhaps, of some degree of steadiness.

Belgian Railways.—In eight years the charges on goods on the Belgian State railways have been lowered on an average 28 per cent; the public have despatched 2,706,000 additional tons of goods, they have economized upwards of £800,000 on the cost of carriage, and yet the public treasury has realized £231,240 profit, after having paid the cost of working and the interest of additional capital.

A new Gauge.—It is proposed, among the schemes for improving London traffic, to make an open railway, with a three-feet gauge, from Islington to the Moorgate Street station of the Underground Railway.

Railways in Hindostan.—Four thousand miles of railway have been completed in Hindostan, and one thousand more are projected or commenced.

NEW BOOKS.

Description of Richards' Improved Steam Engine Indicator; with Directions for its Use. Second Edition Enlarged and Revised. By Charles T. Porter. London: Longmans, Green, Reader, and Dyer.

This is really a treatise on steam and the steam engine. "Engineering" reviews it in a long article from which we extract the following: Most engineers are familiar with a class of works which, whilst professing to be technical treatises or handbooks, are in reality nothing more than neatly worded advertisements or puffs of some particular machine or invention. To such books as these, that forming the subject of the present notice presents a remarkable contrast.

Mr. Porter has divided the second edition of his work into three parts, about half of the second part and nearly the whole of the third being entirely new. The first division comprises four sections, devoted respectively to an explanation of the nature and use of the indicator, to remarks on truth in the diagram, to a description of the Richards' indicator, and to directions for applying and taking care of the instrument. After explaining generally the action of the indicator and the object to be attained by its use, Mr. Porter enumerates the various sources of error which may operate to produce an incorrect diagram, and points out the means by which they may be avoided.

The second part of the book is divided into two sections, the first being devoted to directions for ascertaining from the diagrams the power exerted by the engine, and the second to instructions for calculating from the same data the amount of steam consumed. Both these matters are treated most comprehensively and clearly; and to this part are appended tables of the areas of circles; of hyperbolic logarithms; and of the properties of steam. These latter, which are very complete, have been prepared by Mr. Porter from the results of the experiments of M. Regnault, these results having been converted into English measures.

The third part of the work, which we consider to be even more important than those which precede it, is divided into five sections bearing the following headings: 1st, Observations on the several lines of the diagram; 2d. On the conversion of heat into work in the steam engine; 3d, The rotative force exerted upon the crank the same for all equal divisions of the diagram; 4th, The diagram not a true representation of the pressure on the crank; and, 5th, Of the motion of the piston as controlled by the crank through the medium of the connecting rod. The second section of the third part, that devoted to a consideration of the conversion of heat into work in the steam engine, is entirely new, and it forms, without exception, the clearest description of the mechanical theory of heat and of the action of steam during expansion that we have yet met with. Mr. Porter's remarks are illustrated by a series of examples carefully worked out, and the theoretical action of the steam deduced from these examples is compared with that which is shown by the indicator to take place in practice. In the next section, Mr. Porter shows that the rotative force exerted upon the crank being the same for all equal divisions of the diagram.

The fourth section of the third part, like the two which precede it, is quite new, and it treats on a subject of the greatest practical importance, namely, the influence exerted by the inertia of the moving parts in modifying the transmission of power from the piston to the crank at the different parts of the stroke. This is a matter to which Mr. Porter has devoted a great amount of attention, and the facts which he points out are worthy of being most carefully studied, particularly by those interested in the construction of high speed engines.

The last section of the book treats, as we have said, of the motion of the piston, as controlled by the crank, through the medium of the connecting rod, and it is accompanied by a most elaborate series of tables, showing, for different lengths of connecting rods, the motion of the piston corresponding to each degree of motion of the crank. These tables, which must have cost Mr. Porter an immense expenditure of time and trouble to calculate, give each result to seven places of decimals, and they are arranged in a novel manner. Each table is composed of four columns of figures disposed in concentric semicircles, the position of each particular result in these semicircles corresponding to the angle to which it relates.

Altogether the book is one which no engineer engaged in the construction of steam engines should be without; and least of all those of our profession—and they are now a numerous class—who are interested in what has been termed "high-speed engineering."

The History and Progress of the Electric Telegraph, &c. By Robert Sabine, C. E. London: Virtue & Co.

"Our language," says "Engineering," "is certainly becoming rich in the technical literature of telegraphy. For years it remained almost a barren waste. Mr. Culley first broke the spell, and the success of his work is shown by its having rapidly reached a third edition. Mr. Sabine succeeded, and latterly Mr. E. Bright and Mr. Latimer Clark have enriched the science with very valuable additions. The work before us is a second edition of the first portion of the larger work by Mr. Sabine that was published in 1867, and was reviewed by us in our number of February 15th of that year. Its price and size are both reduced. It forms part of Weale's admirable rudimentary series. Much has been added, some parts rewritten, and a good deal expunged. Altogether it is a considorable improvement upon the original, and it is a book which should be in the hands of every telegraphist, for it supplies a gap unfilled by Culley or Clark."

But the reviewer does not agree with the author as to the respective credit due to the fathers of telegraphy. What the reviewer says on this subject will be read in this country with, as the French say, an "uneasy interest." It is as follows:

"We do not wish to diminish one iota the credit due to Morse for the invention of the simplest, most perfect, and most universal telegraph in existence; but we protest against his being allowed priority of claim. We do not object to his immortality. If ideal conversations are to rank as inventions then should Galileo be called the inventor of the telegraph.

"Morse acknowledges having first received the conception of a telegraph in 1832; Wheatstone had been studying the subject years before this. Cooke and Wheatstone's telegraph was patented in the early part of 1837, and Morse's in the latter part of the same year. The first line of telegraph was erected by them in 1838, and the first line constructed in the United States was put in operation in the month of June, 1844. Cooke and Wheatstone's first 'hatchment' telegraph was a beautiful and practical instrument; Morse's first relays weighed 158 pounds, and required two men to carry them.

"We contend that the author's lights in meting out immortality have not been sufficiently luminous. We say Cooke and Wheatstone first, Morse a good second, Steinheil a bad third, and the rest nowhere."

Suggestions for the Sanitary Improvement of Laborers' Cottages and of Villages. By William Menzies, Deputy Surveyor of Windsor Forest and Parks. London: Longmans, 1869.

Practical Application of the Slide Valve and Link Motion to Stationary, Portable, Locomotive and Marine Engines; with New and Simple Methods for Proportioning the Parts. By Wm. S. Auchincloss, C. E., late U. S. Commissioner to the Paris Universal Exposition, and author of Report on Steam Engineering. 8vo. In cloth; 58 illustrations, with a valve travel scale. Price $2.50.

This work covers a field heretofore but partially occupied, and develops the fundamental principles of a subject over which, in many minds, hovers a cloud of doubt and uncertainty. Such a sense of vagueness is especially felt when one attempts to follow the intricate motions of a link, and to determine what effects different radii, as well as modes of suspension, must have on the character of the valve motion. It also sorely perplexes the student of steam engineering to discover some fixed principle by which he can at all times instantly determine for a simple slide valve and ports what dimensions will satisfy certain conditions, without following the tedious process of either substituting trial ones in several formula, and solving the same over and over again until, perchance, the right valves are reached, or of placing them on a model and noting their effects; or worse yet, by the geometrical construction of a number of ellipses. The first part of the work before us readily solves all such difficulties by means of an ingenious diagram called the "Travel Scale," from which the engineer can directly measure one after another of the desired dimensions with perfect confidence as to the result. Having explained the nature of the fixed single eccentric motion, illustrated with indicator diagrams the manner in which the action of its valve is affected by the angularity of the connecting rod, and furnished simple means for correcting the same, the author treats of the adjustable eccentric, which he makes introductory to the general subject of link motion. His method of investigating the latter is purely a process of geometrical construction. He entirely rejects the idea that algebraic or trigonometric formulæ are capable of here rendering any practical assistance. The plan of procedure is clearly defined and many means explained for varying the results. As the true radius of the link and position of the center of suspension are thereby determined with the greatest ease, the draughtsman can with its aid quickly scheme a satisfactory link motion without resorting to an expensive link model. The shifting, stationary, Allan and Walschaërt link motions are consecutively examined, and their points of similarity compared. The subjects of independent cut-off, clearance, friction, etc., have likewise received due consideration. To the draughtsman, master mechanic and student of steam engineering this little work will prove a most invaluable assistant, not only preventing the occurrence in designs of mortifying mistakes, but greatly economizing the time of execution.

Exposition Maritime Internationale du Havre. 1868. Rapports du Jury International. London: Johnson & Sons.

The rapidity and completeness with which the jury reports of the Havre Maritime Exhibition have been published presents a striking contrast to what we have hitherto been accustomed. It is compiled in two languages—English and French—and contains a complete list of awards as well as the reports of the juries. As to its accuracy we are not in a position to speak, but there can be no doubt of its excellence in a typographical point of view. Every care appears to have been taken to ensure correctness, the proofs having been submitted for final revision to the president and reporter of every class or section, they being held responsible for the accuracy of the awards and the motives assigned for them. The original intention of the promoters of the Exhibition was that it should follow immediately the "Universal" at Paris, and be supplementary to it. The docks at Havre enabled the jurors to establish a species of competitive examination of vessels afloat, and to test the improvements that had been made of late years by inspecting, not merely models on a large scale, but the ships themselves. With few exceptions, all foreign nations, England especially, co-operated by sending liberal contributions. A very novel feature in the Havre Exhibition was the election of the jurors for each class by the suffrage of the exhibitors, an arrangement which proved highly successful. The compilation of this work, containing nearly 600 closely printed pages, must have been a task of considerable difficulty and responsibility. The mode in which it has been accomplished is highly creditable to the publisher, to whom the undertaking was entrusted by the Commission of the Exhibition.—*Engineering.*

The Royal Engineer. By the Rt. Hon. Sir Francis B. Head, Bart. London: John Murray, 1869.

Sir Francis Head certainly deserves well of the Royal Engineers. He has visited Chatham, and has inspected the Mounted Engineer Train at Aldershot, and has committed the results of his investigation to print. It is well that somebody has done so, for otherwise the solid work which is done by the most scientific branch of the army might have passed unnoticed. We now know the composition and working of the photographic and electrical school at Chatham, as well as the whole means which are adopted at the Royal Engineer establishment to train the sappers and miners of the British army in photography, surveying, field works, and the construction of entrenchments. Sir Francis Head describes the Royal Engineer *ab ovo.* He relates how he is first admitted into the Royal Military Academy at Woolwich, educated there, and in a chrysalis state transmitted to Chatham, where he completes his practical and technical instruction. He even describes the various schools at the Engineer establishment, at which the non-commissioned officers and men are prepared for their several duties. Each different species of them requires a separate training and separate instruction. The draughtsmen, the surveyors, the photographers, the electricians, are all subjected to diverse treatments, which are clearly recounted in the book before us. Those who wish to find all that pertains to the preparation of both officers and men of the Engineers for their duties both in the field and at the desk, as well as any who are interested in the requirements for obtaining a commission in that corps, will derive much value from Sir Francis Head's work.—*The Engineer.*

A large, carefully prepared work on military engineering; octavo; 400 pages.

The Elements of Heat and of Non-metallic Chemistry. By Fred'k Guthrie, A.B.(Lond.), Ph. D., F. R. S. E. London: Van Voorst. 1868.

Mr. Guthrie evidently thinks that even elementary treatises like those of Balfour Stewart are of too difficult a character, and that works like that of Lardner are too general for the requirements of the London University. He has, therefore, attempted to compile a book which, while avoiding the mathematical details of higher treatises, should bring together, in clear and intelligible language, the leading phenomena and laws of heat and of non-metallic chemistry. His endeavors have been in some measure successful, and in some degree also have failed in their purpose. For instance, while he has treated the subject of heat in accordance with the aim he had in view, he has fallen short of his aim in dealing with the chemistry of the non-metallic elements.—*Popular Science Rev.*

MISCELLANEOUS.

MACHINE BUILDING IN EUROPE.—There are many and large—some of them very large—engineering establishments upon the Continent, and they appear to be busy, busier than works of the same class in England. Besides the large engine works of the French government at Indret, near the mouth of the Loire; and the large railway workshops of the six great French railway companies, there are, in Paris, the works of Cail and those of Gouin, employing at times, the first 2,000 and the second 1,000, or more, men. There is tho great establishment of Schneider & Co., at Creusot; the fine locomotive works (we have none better nor larger) at Fives, near Lille; the large works of André Koechlin & Co., at Mulhouse; the Graffenstadten works on the Rhine; and, as for marine engine-makers, besides those at Indret, and Schneider & Co's, the large works of Mazaline & Nillus at Havre, and those of the Mediterranean Company at Marseilles. The Creusot works alone employ between 9,000 and 10,000 workpeople in all departments, and few of the others named employ less than 1,000, and some of them very many more.

In Belgium there are the great Société John Cockerill, employing many thousands of hands, the Couillet Company, the Société St. Leonard, and others. In Holland there are the large iron ship-building and engineering works of Paul Von Vlissingen & Dudok Von Heel, at Amsterdam. In Switzerland are large works at Zurich, viz: those of Escher, Wyss & Co., of which Matthew Murray Jackson, an English engineer, is manager; and in Bavaria are the large bridge building works of Klett & Co., of Nuremburg, and the smaller engine works of Maffei, at Hirschau, near Munich. There are extensive engine works also at Carlsruhe, in Wurtemburg, and there are machine making establishments of various degrees of magnitude scattered over a large portion of the Continent.

Borsig, of Berlin, some time since turned out his 2,400th locomotive; he sent his 2,000th to the Paris Exhibition. Experts speak in high terms of the character of Borsig's workmanship, ranking it much above that of the French and Belgian engineers. He employs steel very largely, much of it of his own manfacture, and he gives a high degree of finish, not only to the working parts, but to some others which with us are painted. His contracts are largely upon Russian account. Borsig's large iron works at Moabit, four miles out of Berlin, have been converted into a great boiler factory, and his iron makers are being transferred, to the extent of one thousand families of workpeople, to a new establishment in Silesia.

Hartmann, of Chemnitz, in Saxony, now employs 1,800 men and boys, and is constructing machinery of almost every class. He has lately built an erecting shop, to receive thirty-five locomotives in a single row, and, allowing no more than sixteen feet from center to center of pits, this building must be upwards of 550 feet long. His make of engineers' tools, cotton and woolen machinery, turbines, &c., is very large.

PATENTS.—About 4,000 "provisional protections" are granted yearly at the British Great Seal Patent Office, the protections granted being within, perhaps, a dozen or so of all the applications made. Of these protections only about two-thirds pay the additional £20, which gives them the force of a patent. At the end of three years from the original grant the patent lapses unless £50 more be paid, and at the end of seven years from the grant £100 more must be paid to continue the patent for the full term of fourteen years. In the year ending September 30th last, 14,153 patents, re-issues and protections of designs were granted by the United States Patent Office. Over 20,000 were applied for.

THE INTRODUCTION OF STEAM FIRE ENGINES.—Steam power for extinguishing fires was in use in manufacturing establishments many years before it was employed on portable machines. Every factory of any pretensions had its steam-driven pump with hose and other attachments calculated to reach every portion of the establishment. About the year 1829 or 1830, Capt. Ericsson, then of the firm of Braithwaithe & Ericsson, London, England, built and exhibited a portable steam fire engine. In 1842 or 1843 he produced a similar engine in New York city, and it was tested but never brought into regular service. The writer remembers a great objection urged against its use, that it burst any hose that could be made, which showed that the fault of want of success did not lie with the machine.

So far as we are informed, the credit of overcoming prejudice and successfully introducing the steamer in cities and large towns belongs to Miles Greenwood, when mayor of Cincinnati, Ohio. Mr. Greenwood, being a man of great tenacity of purpose and a thorough mechanic, and having, moreover, the confidence of his fellow citizens, succeeded where only failure awaited others; and, in consequence, Cincinnati was the first city to adopt the steamer as a permanent portion of its fire department force.

The reasons why this most efficient agent—steam—was not sooner utilized for the protection of property from fires, may be summed up in one word, prejudice, prejudice born of ignorance. Fire and steam careering through the streets instead of inducing confidence and a feeling of security, inspired terror or created apprehension. Our municipal authorities, too, are not generally engineers or mechanics—and—the steamer does not vote.

The metropolitan fire department of New York city numbers 34 steamers of about 50 H. P. each, equal to 185 men, or, in the aggregate, 6,290 men, while the actual number of men employed, even adding the 12 hook and ladder companies, is only about 550: thus relieving 5,740 men from the labors, dangers, and the exposure of the fireman, and allowing them to become producers rather than merely protectors of property. The time is past to question either the superior efficiency or tho economic advantages of the steamer over the hand engine. As well might we return to the old hand press and the spinning wheel, print our newspaper editions of 100,000 daily and clothe the teeming millions by hand labor, as to discard the powerful agency of steam in the protection of our property from fires.—*Scientific American.*

NEW GALVANIC BATTERY.—A new battery is announced as arranged by M. P. Guyot, which may be useful for telegraphic purposes and electrical alarms. It consists of a porous earthen vessel filled with finely-powdered iron ore, in which is plunged a cylinder of gas retort charcoal and an ordinary vessel filled with concentrated solution of common salt, in which is placed a slip of zinc. The only care required to keep such a battery in order is to keep the latter vessel always full of concentrated solution.—Further, the solution may be replaced by sand impregnated with it or by salt in crystals, the humidity of the atmosphere being always sufficient to serve as a solvent. If the latter form be found to answer, the battery would be extremely convenient on shipboard, in trains, or wherever there is motion.

A MUCH NEEDED BOOK.—Our publishers have many inquiries for a work on the *American Steamboat Engine,* containing engravings (not necessarily costly) and details of valves and valve gear, and other parts and their working. A book is wanted that will teach a mechanic having some theoretical knowledge or a student having some practical ideas, how to set the valves and operate and maintain this kind of engine to the best advantage.

The American Master Mechanics' Association.—We take pleasure, says the "Western Railroad Gazette," in laying before our readers a few facts connected with the objects and operations of the American Railway Master Mechanics' Association, now approaching the third year of its existence. This association is composed of the master mechanics of the railways of the United States, whose object is that of improving the motive power of the several roads which they represent, and also determining the best and most practical as well as the most economical system of construction and management thereof. For this purpose committees are appointed among themselves to report upon the different subjects connected with their department of railway management. These reports and the attendant discussions are published for the benefit of the railways at large. We are confident that no mechanical association has been found comprising a greater degree of practical intelligence; and when it is borne in mind that this report will embody the combined experience of over two hundred of the ablest mechanics and engineers of our country, it will at once be understood how valuable a text book these reports will make. Mr. L. P. Dodge is the secretary of this committee, and is now making the tour of the United States, visiting each master mechanic, and, in per on, procuring data and information for the required reports. Perhaps the most important committee for the coming year is that upon "boilers," composed of Messrs. Hayes, Illinois Central Railway; Jauriet, Chicago, Burlington and Quincy Railway; and Anderson of the Chicago and Northwestern Railway; as it is to take up the question of *steel plates* as a substitute for iron or copper, and we are informed that thus far the experience of many of the largest roads is largely and unmistakably in favor of its use, especially in coal-burning locomotives. Their next meeting is to be held at Pittsburg in September, due notice of which will be given.

Bleaching of Wood-Pulp for Paper.—M. Orioli, a French chemist, says, in the "Revue Hebdomadaire de Chimie," that the chloride of lime, if the dose is the least in excess, has a tendency to give a yellow tinge to the pulp; that all energetic acids, without exception, tend to give a reddish color to the paper when exposed for a long time to the effects of the sun or of moisture, and that the least trace of iron is sufficient in a very short time to blacken the pulp. He says he has succeeded in avoiding all these inconveniences by the use of the following mixture: For a hundredweight of wood-pulp, he employs 400 grammes (four-fifths of a pound) of oxalic acid, which has the double advantage of bleaching the coloring matter already oxidized, and of neutralizing the alkaline principles which favor such oxidation; he adds to the oxalic acid one pound, or a little more, of sulphate of alumina, entirely deprived of iron.—The principal agent in this mode of bleaching is the oxalic acid, the power of which over vegetable coloring matters is well-known; the alum has no bleaching power of its own, but it forms with the coloring matter of the wood an almost colorless lake, which has the effect of increasing the brilliancy of the pulp.

The Effect of Cold on Tin.—It is stated in a recent number of the "Comptes Rendus," that according to Herr Fritsche, tin exposed at St. Petersburgh last winter to a temperature of 40° below zero was converted into a semi-crystalline mass containing cavities like basalt. In masses of tin weighing from 55 lb. to 66 lb. these cavities in some cases had a volume amounting to nearly 24 cubic inches.—According to M. Dumas facts of this kind are not new in Russia; for instance, in one case the pipes of a church organ were so altered by the cold as to be no longer sonorous.

New Horse Shoe Machine.—Some interest has been excited in Birmingham by a new machine for the manufacture of horse shoes, invented by M. Bastien, Paris. The principle of the invention is the hydraulic press. The process is as follows: Immediately the bar comes red hot from the furnace the iron is transferred to the rolling mill. Here a movable piece on which the bar is placed receives an alternative motion from two pistons of the hydraulic press. This movable piece presses the bar between two left-hand sliding surfaces, which impart to it a bend. It is next very strongly pressed on a die, thus receiving the definite form, while at the same time the nail holes are pierced, and by means of a spring the movable piece recedes and allows the finished shoe to fall out into a shallow tank of water placed underneath. The action of the machine suffices to make a shoe at each motion, forward and back, thus preventing any waste of power. The dies and stamps are easy of adjustment, and may be immediately exchanged for the production of larger and smaller shoes at discretion. Two pressures are necessary, namely, one of from four to five atmospheres to produce the form of the shoe, and another of from 100 to 150 atmospheres to pierce the nail holes. A movement of from six to eight strokes per minute can easily be obtained by this machine, producing as many shoes as strokes. The success which has attended the invention on the Continent is likely to be supplemented in this district by ironmasters at present engaged in the production of horse shoe bars.—*The Engineer.*

Value of European Patents.—The American origin of an invention is now a recommendation in Europe, where many of these inventions are in successful operation, and large fortunes have been realized by their introduction. Improvements relating to some manufactures are of great value in this kingdom. Mr. Bessemer derives an annual income of about $2,000,000 from his British steel patents, and the patentee of a device for dressing mill-stones, by a revolving diamond, has realized over $1,000,000 the first year of his patent. The use of a diamond for this purpose is an American invention, and the estimated value of the exclusive right in England, for ten years, is $5,000,000. British patents, as a rule, are the most valuable, but many inventions are equally profitable in other parts of Europe, and some are peculiarly adapted to continental wants and customs.—*Hazletine, Lake & Co's Circular.*

The California Big Trees.—Within a space of fifty acres, in the Original Grove, there were (in 1865), 103 trees of great size, twenty of which exceeded twenty-five feet in diameter at their base. The "big tree stump" had room enough for thirty-two persons to dance four sets of cotillions at the same time; besides many musicians and spectators. Across the solid wood of this stump, at 5¼ feet from the ground (*without* the bark, which equalled 15 to 18 inches in thickness), it measured 25 feet. This glorious tree was sound to its center, and was 302 feet in height and 96 feet in circumference at the ground. The "Father of the Forest," the *largest* tree of the entire group, measured in circumference, at the ground, 110 feet.

German Locomotive Prices.—Herr Borsig, of Berlin, has recently received an order from the Rhenish railway for twelve locomotive engines and tenders for working passenger or goods trains. The engines weigh, empty, thirty tons, sixteen cwt. and the tenders eleven tons, four cwt; the price of each engine and tender is £2,625.

The Heaviest Lathe.—The Lowell machine shop is now building the heaviest turning lathe in the country, to weigh seventy tons.

PERMANENT WAY.

REPORT OF THE STATE ENGINEER OF NEW YORK. PREPARED BY S. H. SWEET, DEPUTY.

From the advance sheets of the Report of the State Engineer and Surveyor of New York, on Railroads.

The following timely, able and practical considerations form a part of the State Engineer and Surveyor's Report for 1868 upon Railroads. Official reports upon such subjects are often valuable in their details, but it is not often that a government engineer reads a sound, practical lesson to our railway managers and railmakers. Mr. Sweet obviously understands the mistakes that have been made and the ends that should be sought in both these departments, and he does not hesitate to characterize them in plain language. We copy, on this occasion, his remarks on Road-bed, Sleepers, Joints and Iron Rails. In a future number we shall quote the report on the subject of Steel and Steel-headed Rails.

Increasing Demand for Permanence of Way.—The statistics of European, as well as of American railways, clearly indicate that any notable economy of working and maintenance must be accomplished chiefly through the improvement of railway *tracks.* The renewal of rails is the largest item in the cost of maintaining a railway, and the modern system of running heavy trains by much heavier and longer engines, is throwing more work upon the rails every year. The increased *articulation* of locomotives, so as to relieve the lateral strains upon the road and the individual weights upon the wheels, though promising well, is yet experimental. When fully worked out, it will also lead to a still greater loading of trains, for in the other departments of working a railway, economy lies in the greatest possible concentration of power, attendance and labor. So that, however running gear and steam machinery may be improved, the permanent way of trunk lines, at least, always will be, and probably should be, worked to its full capacity. In fact, the strength and durability of a given track is the feature that limits the amount, and hence the economy of the transportation that can be done upon it.

But there is another and more formidable destroyer of permanent way than weight, and that is speed. The running time of our passenger traffic, instead of being shortened as the distances to be reached were increased, has been lengthened, as compared with the speed of ten or fifteen years ago. Whatever risks and expenses rival lines may have adopted in other particulars, they have harmoniously abstained from running fast trains. *This* is a bid for patronage, which the most reckless manager has not dared to make. The public have tolerated this state of things longer than could have been expected. There is now a general and growing demand for fast trains. The time of one individual is worth more than it was when railways were introduced, and thousands of individuals travel now where dozens traveled then. In view of the opening of the Pacific railway, the development of the vast and growing States of the far west, and the steady tide of business and pleasure travel from these distant regions to our seaboard, the economy of fast trains is to be counted by days instead of minutes. To meet this requirement, the first and heaviest demand must be made upon the permanent way. The steam engine and the vehicle may be adapted to high speed with comparative ease and economy, but every rail, every joint and every sleeper, from the Atlantic to the Pacific, and between all the centers of population, must be maintained in a condition not only to bear fast trains safely and smoothly, but to endure the quadrupled strains and percussions due to a doubled speed.

Every increment of "work done" upon a railway, every increase in the weight, number or speed of the wheels, every economy of concentrating labor and power, brings an increased demand for endurance directly upon the permanent way. And, indirectly, the quality of the permanent way determines the economy of power of traction and of maintenance of engines and rolling stock.

In the construction, of new lines, a vast economy in earthworks and viaducts may be obtained by means of heavier grades and curves, but at the expense of increased wear and tear of permanent way.

The desirableness, if not the necessity, of increasing the durability of our railway tracks, even to meet present demands, is the truth of all others that our railway managers do not require to be told. The object of the foregoing remarks is to remind them that this necessity, instead of decreasing, must constantly and rapidly increase, as traffic grows and railways reach out into the wilderness.

Drainage, Ballast, Etc.—The improvement of the road-bed, by means of better drainage and ballasting, although of very great importance, presents no engineering difficulties. The practice and the economy are well settled, and it is simply a question of spending a shilling to save a pound.

Sleepers.—The preservation of sleepers by chemical processes, is always the subject of experiment on one or another of our railways. The practice, however, is not general in this country, because the mashing of the rail into the sleeper usually destroys it in advance of decay. In England, the bearings of the chairs used (with the double-headed rail) on every sleeper, are so extended, that the mechanical injury of the wood is quite small; prevention against decay—usually immersion in coal tar—is therefore generally practised. The insufficient bearing offered by sleepers to the rails, is thus, directly and indirectly, the cause of their rapid destruction. It is stated that placing the sleepers closer than, say two feet apart centers, would prevent the convenient tamping of the ballast. It is objected to the longitudinal sleeper, that the rail, lying parallel with the fiber of the wood, mashes into it more easily than into the cross sleeper. These objections to sufficient bearing, are not inherent in either system, but arise from improper construction. Thoroughly good ballast would not require continual tamping. It is even proposed by some of our most experienced engineers, to cover the ballast with a coating of coal tar and gravel, to absolutely exclude water, and thus to prevent not only decay, but washing, freezing, heaving, settling—all destroying elements but vibration and wear. In this case, the timber bearings under the rails should be almost continuous, to prevent wear both on the ballast and on the rail. The mashing of rails into timbers, either longitudinals or cross sleepers, is largely due to the want of stiffness in the rails themselves. The low ∩ rails on the Great Western of England, are the most notable examples of this kind of failure. If the iron wasted in the thick stem and pear head of our worst shaped rails, were put into the *height* of stem, their resistance to deflection would be doubled, this resistance being as the cube of the depth.

There is a growing conviction among engineers, that the longitudinal system will become standard. It offers twice to three times as much bearing for the rail as the cross sleeper system. The whole strength of a longitudinal is added to the strength of the rail, considered as a beam to carry the load. The strength of the cross sleeper in this direction is wholly wasted. The longitudinal is almost certain to prevent the displacement of a broken rail. This system has never been tried on a large scale, with a high, stiff rail. It requires better ballast and more thorough adjustment than the other system. Independent points of support, like the isolated ends of cross sleepers, that can be blocked up or let down at pleasure, without reference to the rest of the superstruction, are the indispensable accompaniment of bad ballasting and imperfect drainage. But they are unsuited to any system of homogeneous, continuous and *permanent* way.

Iron sleepers are coming into use in countries where timber is very costly and unsuitable, and are the subjects of various experiments in England. The great defect of all imperishable sleepers, whether stone or iron, has been want of elasticity. An anvil under a rail, and especially under a joint, is almost worse than an insufficient support. The failure of stone blocks on the Lowell, Camden & Amboy and various English lines, is often quoted to prove that rails cannot be laid on a stable and durable foundation. This is a most serious mistake. An inch thickness of wood between a driving-wheel rim and a tyre, doubles the endurance of a wheel; a quarter of an inch of rubber confined in a suitable chair allows the laying of rails upon stone blocks, without extraordinary wear. A great range of elasticity, or a general giving-way of the road-bed are not required—only an imperceptible yielding to the minute, but incessant vibrations known as jarring, which would otherwise destroy the whole fabric. A pocket cut in a stone block or cast in an iron sleeper and filled with a cushion of wood or rubber would afford all the elasticity required.

Rail Joints.—The selection of joint fastenings for the ends of rails is somewhat dependent upon the weight of rail required and hence upon the traffic. After twenty years of competitive trial with every variety of fastening, the simple fish-joint—an iron splice on each side of the rail—has become standard in Europe and is gaining ground here. It is the lightest and strongest fastening that can be applied, when rails are high and properly shaped to receive it. The old difficulty of nuts jarring loose, has been overcome by the use of elastic washers. Fishing a pear-headed rail three or three and a half inches high, would be perfectly useless. For light rails, and for steel rails (to save weakening them by punching) and as an auxiliary to the fish-joint, the new Reeves' fastening—a tight clamp upon the contiguous flanges of two rails, is coming largely into use. The mere chair or seating for the ends of rails is no longer considered safe nor economical for lines of heavy traffic. Although there is room for farther experiment, it cannot be said that the demand for a good rail-joint has not been met.

Iron Rails.—Some of the early rails put down in this country on roads of considerable traffic, lasted over twenty years, most of this service having been under light vehicles, but upon indifferent road-beds. These rails finally *wore out*—they did not laminate to any great extent. We have the specifications by which these rails were made, and we know the quality of the material put into them. Good iron without any admixture of old rails, was welded under the hammer and then reheated and reworked until it was made fine grained and compact in the highest degree.

It is often asked why we do not get such rails now. The answer is that they are never called for. It does not appear from any accessible records, that such a pattern, or such a specification, or such a price, or such a service have been contemplated in any modern specification. The old patterns were very thin and elastic in the head. The pear-head was an abortive invention to work off bad iron. The old rails being low and sound, could bend without injury, but as this extreme deflection would keep modern heavy vehicles constantly traveling up hill, heavier rails have been specified; 60 and 65 lbs. instead of 40 and 45 lbs. to the yard, thus increasing the difficulty of manufacture and the stress on the material.

Better iron rails can be made now than were ever made before: first, because our knowledge of impurities, fluxes, processes, characteristics and requirements has been enlarged. More suitable and more uniform iron can be produced. Second, because forge and rolling-mill machinery is heavier and better than of old. Greater refinement and condensation and closer welds can be made by modern hammers and rolls.

But rails made from suitable iron, such as would be used for axles and forgings—rails rolled from hammer-welded and reheated piles—would cost nearly as much as steel rails. In fact, rails of ordinary iron with heads of puddled steel (which is a high wrought iron made from the best material) are sold at $115 per ton.

American railway managers, instead of offering anything like cost for good iron rails, have made themselves notorious by establishing as standard, a brand of rails known all over the world as "American rails," which are confessedly bought and sold as the poorest, weakest, most impure, least worked, least durable and cheapest rails that can be produced.* Although American made rails are usually better, and although the more enlightened managers willingly pay higher prices to home makers, yet the general tendency has been to reduce prices to the lowest possible point *irrespective of quality*.

No specification is made, no test institut-

* See report of A. S. Hewitt, U. S. Commissioner to the Paris Exposition.

Also see letter of Mr. C. P. Sandberg, to the "London Times," in "Engineering," Jan., 1869.

ed, no care taken, except to find the lowest bidder, and he may use all old rails, cut up and laid in the rail pile, without breaking down, reheating or admixture, if he can only make them stick together till they are delivered. This is what the rail maker is hired to do, and he does it openly, but under protest.

A leading railway president and reformer, Mr. Hinckley, of the Philadelphia, Wilmington & Baltimore railway, says:* "There is great fear on my part that railway companies will themselves tempt steel makers to send a poor article, by buying the cheapest—first cost only considered—as they did with the iron masters. It rests with railroad men to keep steel rails good by buying no poor ones."

In order to meet the demand for cheap rails, our iron masters have introduced a poison into our railroad iron, from the effects of which we shall very slowly recover. Under the pretence of making the heads of rails hard and durable, they have made them of a cold-short iron, impregnated with phosphorus. Now as it is notorious that rails go to pieces chiefly by lamination—by weakness of materials and welds, the hardness of the head is not much utilized. But the disease reaches its climax in the next generation of rails. The old rails are cut up, piled with raw iron and rolled into a new rail. The phosphorus is now distributed throughout the mass, contributing both to bad welds and to cold-shortness where strength is most required. One slab of good fibrous iron is indeed placed at the bottom of the pile to form the flange; but, to balance it, a layer of phosphorus is put on the head.

As long, therefore, as old rails are used promiscuously in the proportion of $\frac{1}{3}$ to $\frac{2}{3}$ with new iron, it is impossible to guarantee new rails against breaking and rapid lamination. When old rails are selected by the fracture, and rolled into bars before being piled; when the new iron is selected for its quality and not for its cheapness, and when the top slabs are welded by the hammer and then reheated and rolled, good rails may be made out of the materials at hand, but at a largely increased cost.

Inasmuch as railway companies are not always satisfied with the representations of rail makers, as to cost, quality, etc., a plan has been suggested whereby inaccuracies of this kind are not likely to occur. A specification of iron and manufacture is to be agreed upon and to be carried out under the inspection of the railway company's engineer. The actual cost as shown by the rolling mill books, together with a certain price (not a certain percentage—for obvious reasons) per ton for wear and tear and profit, to be the price of the rails. In this way it is not possible for the consumer to demand features for which he is unwilling to pay, nor for the maker to profit by working in poor materials.

There is a remarkable difference in the wear of iron rails on our different lines, and this difference is almost in exact proportion to their cost. When traffic is so light that good iron rails will last from seven to ten years, and when the money to buy a better material cannot be raised, as in case of many new lines, the question of better iron rails is of the greatest importance. But for lines of heavy traffic, like the New York Central, Erie and Hudson River, no iron rail, however made, can meet the demand. At something less than the cost of steel, an iron rail can be produced that will wear out instead of going to pieces in the welds; but it will be so much softer and less homogeneous than steel, that the latter will be as great an improvement upon good iron, as good iron is upon the bad iron now in use. The wear of steel *tyres* is three or four times greater than that of the best iron tyres. It would obviously be impossible to make an iron rail superior to a Lowmoor iron tyre.

(To be continued.)

THE LATE ORDNANCE COMMITTEE.

For "Van Nostrand's Magazine."

The late Joint Committee on Ordnance of both Houses of Congress was a body of men intrusted with the powers of Congress, representing the people and States of the country sitting in inquest over the acts of other public servants, and charged with the duty of enlightening Congress and the people as to the honesty and efficiency to be found in an important branch of the public service. The report they submit purports to be the unbiased verdict of six able men of high intelligence, having at their disposal unlimited sources of information, and the advice of all the experts in the world. The subject they are to investigate is one of peculiar interest, for it is a branch of special

* Letter of December 22, 1868, to Edward Austin, Esq., Boston. See "Van Nostrand's Engineering Magazine," for April, p. 367.

requirement upon the successful administration of which largely depends our military prestige, and, by consequence, the standing and respect we are entitled to among other civilized nations. It is to be fairly presumed the verdict of this inquisitorial body will carry with it great weight among those who look merely at its surface, and those who do so are the great mass of the American people, who keep themselves informed respecting the actions of Congress. The undercurrents are unfortunately hidden. The motives and the evidence are seldom seen. Since upon these turn the whole value and significance of such a document, and they being carefully kept out of sight, as far as practicable, the power for harm and the wreaking of private malice are boundless in the hands of such a committee; and, it may be added, the criminality of deliberate falsehood all the greater.

It was this same committee which, last year, brought in a damaging report against the Chief of Ordnance—Gen. A. B. Dyer—charging that officer with having availed himself of his high position for his own private advantage; of having received private emolument for furnishing ordnance stores of inferior quality when a better quality was being offered; of suppressing the records of the ordnance officer when called upon to furnish evidence, and other charges too numerous to mention. By implication they also assaulted the whole system of American ordnance, and the present constitution of our ordnance service. Under the circumstances, the Chief of Ordnance, who had not been permitted to appear by counsel before the committee, or even to know the drift and character of the investigation, instantly applied for a Court Martial, which was refused, but a Court of Inquiry afterwards granted, consisting of Gens. Thomas, Hancock, and Terry. This court is now near the close of its labors, which have been assiduous and almost unintermitted since last November. The counsel for the prosecution is Clifford Arrick, Esq., formerly an examiner in the Patent Office; subsequently the agent of a New York firm for the manufacture of a patent projectile (the Eureka), of which Arrick is nominally or really the patentee, and W. S. Kennedy, Esq. The counsel for the defence are David D. Field, Esq., of New York, Col. S. V. Benèt, and W. A. De Caindry. The investigation has been most exhaustive upon all the points brought up by the committee. The first volume (a formidable one), and advanced sheets of the second are before us, and we have read them with great interest.

The main points established by the evidence—established, in great part, by the testimony extorted from the prosecutors, beyond a shadow of question, are:

1st. The committee was chiefly constituted of members utterly hostile to the Army in general, and to the Ordnance Department in particular.

2d. The examination was conducted at the instigation of a ring of disappointed contractors, chief among whom were Clifford Arrick, Norman Wiard, and Horatio Ames, and who were allowed every facility and license for entering testimony.

3d. That all persons sympathizing with, or interested in the Ordnance Department, were carefully kept in ignorance of the specific objects of the investigation, and from a full knowledge of the testimony; copies being refused to Gen. Dyer, as well as counsel to represent him, in an examination where the plaintiffs were superabundantly represented.

4th. The mutilation of evidence, the suppression of important facts and interpolation of ideas never intended to be conveyed—done chiefly by this same Arrick, who was clerk !! to the committee, and intrusted with the task of *systematizing* and "boiling down" the evidence, as he expresses it.

5th. That Gen. Dyer has not been pecuniarily, or otherwise personally interested in any contract or official transaction, nor is there the remotest trace of evidence that he ever received any benefit from any official transaction, or suppressed any evidence.

6th. That the report abounds in assertions and criminations, which the evidence, garbled, distorted, and prejudiced as it is, does not warrant under the most unfavorable construction.

7th. The final report of the committee was framed, drawn up, and written entirely by Clifford Arrick, as he himself acknowledges.

The proof of the first point will be perfectly clear by mentioning the names Butler, Schenck, Logan, and Howard. Senators Drake and Cameron were on the committee, but were seldom in the committee room, and had no share in it beyond a silent assent.

The proof of the second is in the correspondence between Ames and Arrick, which was before the court, and contained the details of the conspiracy and reports of progress.

The proof of the third appears in the testimony of Mr. V. E. Smalley, a clerk of the committee, which is perfectly explicit, and in the correspondence between Senator Howard and Gen. Dyer.

Of the 4th, the following is a single specimen out of many; being in relation to an attempt to show that Dyer was the real patentee of the Absterdam projectile, and Absterdam only the ostensible patentee:

Q. to Absterdam by Arrick: "I desire to know whether, in answer to a question put to you before the Joint Committee, you did not say, 'In reality I am not the inventor of two shells, but I am the maker of two shells, known separately to the Ordnance Bureau?' " * * *

Answer. "I wish the court to allow me to state that that evidence of mine in this book is mutilated; that evidence is a forgery; that evidence is manipulated to read differently from what it ought to; other words have been substituted for the ones I used in my testimony. I repudiate it. I said, "In reality I am not ONLY the inventor of two shells, *as I have three patents for improvements in projectiles*, but I am the maker of two shells known separately to the Ordnance Bureau.' " * * *

Q. "When did you write that down in the manner you have just read?"

A. "This morning, sir"

Q. "Who suggested that to you?"

A. "I suggested it to myself before I came here to Washington, when I read the evidence in New York. I was so disgusted with it, I meant to have the matter known if I only had an opportunity. That is not the only specimen. If I were allowed to digest it, and if I had the time, it would make a different story, so far as my evidence is concerned." [Mr. Absterdam then points out three more instances of flagrant mutilation.]

The reports of officers upon the relative merits of the Eureka and other projectiles, upon which important matters were made to turn, and charges based, were shown to have been grossly perverted in the hands of the committee by the production of originals in evidence before the court.

With respect to the 5th point, it will suffice to say that the prosecution do not even attempt to show that Gen. Dyer ever received any benefit from official transactions, and as for the suppression of evidence, the charge was shown to be as cool a piece of deliberate falsehood as we ever heard of.

As to the 6th, we have not room to specify, but can promise the most absolute proof and satisfaction in referring the inquirer to the record of the court.

Arrick's own testimony is categorical respecting the seventh point.

It is to be regretted that the inquiries of the court cannot be extended also to the *recent* report of this committee. But the exposure of the animus of the first report may discredit also the second, and possibly a brief examination of the latter may serve to put it into its proper connection. It seems that Messrs. Arrick, Wiard and Ames, after their success in getting Gen. Dyer in limbo, proceeded to the next step, viz: a more sweeping and explicit indictment of the whole Ordnance Department, and a condemnation of its material. So far as the committee could help them, they succeeded here also. The third step—their abolition and a substitution of a regime of their own—a Board under control of civilians (*i. e.*, of Arrick and Wiard), has not yet been taken and is not likely to be.

I. The report (February 15th, 1869), begins by the astonishing statement that the increase of calibers necessitated by modern warfare has "developed a remarkable and puzzling fact, viz: that systems of fabrication which, with small calibers, gave good endurance, when applied to large guns, proved to be failures." The committee, it seems, wish to express their ignorance of the first ground rule of constructive mechanics, that with an increase of dimensions the strains increase in a higher ratio than the strength—a principle as applicable to guns as it is to girder bridges. Thus, other things being equal, the intensity of the force of the powder will bear a definite ratio to the length of the shot. This force, acting upon a long shot, has to overcome the inertia of a greater amount of metal per square inch of surface in the base of the shot than when acting against a short one. Since an increase of caliber involves an increase of length in the projectile, the intensity or amount per square inch of explosive force increases accordingly. *How "puzzling!"*

The report proceeds:

"Elaborate experiments, stretching over a period of years, have been carried on in Europe and America to solve this problem, and many new systems which in theory promised success have been successively tried and abandoned, nearly all of them succeeding in small guns but failing in large ones, and failing, too, in a manner which increased the complications of the problem—a gun frequently enduring over 2,000 rounds, while another, precisely similar, would explode after a few fires—while guns made of the strongest material seemed generally to prove the weakest when put to the test. No nation at present has guns of large caliber, the endurance of which can be estimated with any degree of certainty. This difficulty, serious enough with smooth-bore guns, is greatly increased in rifles, the 30-pounder being the largest rifled gun that has exhibited even comparatively good endurance in this country, *while in Europe no more satisfactory result has been obtained*."

According to their own showing then, although thousands of dollars have been expended in Europe on ordnance experiments where one has been expended here, and though Europe has machinery which this country will not have for many years to come, we are, after all, *not behind* any nation in the world in respect to ordnance. Speaking of "strongest materials" proving weakest, the committee, I presume, refer to wrought iron and steel—metals not used by the Ordnance Department, except the former for the 3-inch rifle. We thank the committee for this unintentional assent to our practice, which is the use of cast iron. Touching the remark upon the inequalities of endurance of similar guns, we are very curious to know upon what evidence this assertion is founded. Imperfections are as liable to creep into individual guns as into any other mechanical contrivance, in which case the cause of failure may be discerned by inspection. Lastly, the value of the assertion that no nation has a reliable system of heavy ordnance turns upon the word "reliable." If it means that no system has been devised by which we can warrant a long life to every gun fabricated on it, whatever the size, as a mathematical certainty, we assent. The committee might also have suggested, in the same connection, that we have no "reliable" steam boilers, no "reliable" ships, no "reliable" railways—in short, that the millenium has not come. There is no more reason why an infallible gun should be expected of the Ordnance Department than infallible wisdom from an ordnance committee. We have no objection to a comparison of fallibilities. We hope to show before we are done that if our guns are not absolute perfection, and do not preclude the possibility of improvement, they are decidedly superior, in respect both of power and durability, to those of any other system of ordnance in any nation of the world.

II. The report then proceeds to state that the idea that rupture is produced merely by the explosive force of the powder is an error, "as is shown by the fact that the pressure of powder has been found to be uniform, as it gives a uniform range to the projectile, and at times does not burst a gun made of weaker material than others which have burst when fired with like charges." This is mere ignorance on the part of the author of the report. The pressure has *not* been found to be uniform, or anything like it. It is subject to the widest variations, not only as between guns of different calibers (which is obvious enough on principle), but as between guns of the same caliber and pattern. Uniformity of range does not by any means warrant the inference of uniformity of pressure. Indeed, this pressure is regulated by the grain and quality of the powder, and the grain may be so selected that in the average results of an indefinite number of trials, all degrees of pressure may be obtained at will between widely separated maxima and minima limits, while the range remains constant. But in rifled guns there is another source of variation, even with identical charges, viz: the enormous friction of the shot against the bore, to which may be added the length of cartridge and the unequal times required for complete ignition. All practical artillerists, who are well acquainted with experimental firing, are familiar with these causes and know the existence of wide variations in the pressure, as indicated by the pressure gauge. The following citation from experiments made at West Point on a 100-pounder Parrott (see "Holley's Ordnance and Armor," pp. 478–481), illustrates the matter:

CHARGE 10 LBS. OF POWDER; ELEVATION 5 DEGREES; PROJECTILE $99\frac{1}{2}$ LBS.

No.	Powder.	Range.	Pressure.
1	Dupont 7	2,078	38,000
2	Dupont 7	2,180	45,300
3	Hazard 7	2,251	80,000
4	Hazard 7	2,308	86,000
5	Bennington 5	2,221	27,500
6	Hazard cake	2,370	114,000

CHARGE 10 LBS.; ELEVATION 15 DEGREES; PROJECTILE 100 LBS.

No.	Powder.	Range.	Pressure.
13	Dupont 7	4,830	32,630
15	Hazard 7	4,911	48,700
17	Dupont 7	4,796	60,350
18	Dupont 7	5,030	64,000
20	Hazard 7	4,735	99,002
21	Hazard 7	5,045	102,980

These two selections are but samples of what may be found in every experimental record with rifled guns. They show conclusively that range alone is no measure of the pressure. As the committee cite no other "facts" to sustain their assertion we fairly infer that they have none to cite.

III. After mentioning the various European systems and pronouncing them failures, the report declares the Rodman guns failures with the rest, and in proof quotes the report of the Chief of Ordnance of the Navy, who says:

"Opinions differ quite as widely in regard to the preferable mode of developing ordnance power, whether it shall be by smooth or rifled bores, by loading at breech or at muzzle, made from iron, cast or wrought, or from steel, solid or in connected parts. The relation of mass to velocity is also unsettled. In fact the question involves the necessity of going back to fundamental principles, and starting thence by well conducted experiments."

In other words, the statement of the Chief of Ordnance of the Navy, that "opinions differ as to the best mode of developing ordnance power," is proof that the Rodman guns cannot do what is expected of them. Really Jack Bunsby's logic is getting to be very commonplace.

IV. The reader will, therefore, appreciate the force of the remarks which follow this profound criticism of the expert committee:

"It, therefore, appears that, notwithstanding a long series of experiments extending over a long period of years, and the practical experience of our recent war, the ordnance officers of the government have not yet determined upon even the fundamental principles of their art, and possess no positive knowledge of the problem they have so long sought to solve. Mechanics is an exact science, and ignorance of that branch of it involved in the construction of guns would seem to show either want of knowledge of its principles, failure to understand their application, or superficiality of investigation, surprising in men whose minds have been from boyhood trained in the direction of a specialty."

These remarks are highly edifying, coming as they do from a committee, who begin their report by confessing ignorance of causes of failure in large guns as distinct from small ones,—assert that rupture is not due to the expansive force of powder alone,—that range is a measure of the pressure, and that the Rodman guns are failures because the Chief of Ordnance of the Navy says "opinions differ as to the best methods of developing ordnance power!"

In support of the assertion that each system of guns introduced has failed in practice, General Gilmore is represented as reporting that while only twenty-two large guns were mounted at Morris' Island at one time, fifty in all burst during the siege. This is not true. That report states that twenty-four burst, and this number includes a 30-pdr. which had been fired 4,606 rounds at a high elevation,—the most remarkable test, doubtless, on record, of any gun,—and several 100-pdrs. which had been fired more than one thousand rounds—an ample endurance for any rifle of that caliber. We shall speak of the Parrott guns further on.

The statement that Admiral Porter declared that all the Parrott guns used in his fleet to bombard Fort Fisher had burst is, we believe, literal; but the gallant Admiral, as the committee might have known, and probably did know, officially retracted this statement, and paid a high tribute to them on a subsequent occasion. However that may be, how do the committee sustain the charge of failure upon *all* systems when they have only attempted to quote the record of the Parrott system?

V. The next step is an attempt to show that the rupture of guns is due to molecular tension, caused by the heat of rapid firing, which, they say, assists the explosive force of the powder. Here, gentlemen, readers of the "ECLECTIC," is the "cat in the meal." To nine-tenths of you probably this startling hypothesis is no stranger. The pertinacity and self-assurance with which it has been urged by its author, has not allowed many people to remain in ignorance of it. After years of untiring solicitation, of persecution of every variety of government official; in spite of the reticence, or patient refutation, or ridicule, or snubbing, according to the temperament of individuals, which he had always encountered, he has persisted in urging it, and has at last found two advocates. One is Mr. Benj. F. Butler, and the other the editor of "The Tribune." We congratulate Mr. Norman Wiard. He has hit upon the persons of all others best qualified to champion this new revelation of his, which is to overturn all the systems of warfare now in vogue throughout the world. Surely the brilliant projector of the Dutch Gap canal, of the Fort Fisher powder boat, and the advocate of Col. Serrell's flying machine, is, of all men, the one best qualified for, and congenial to the task of convincing the world of Mr. Wiard's heat theory. We regret it should ever be necessary to speak seriously of such a matter. But it is useless to deny that Mr. Norman Wiard, the laughing-stock of every expert and engineer who has heard his name (and most of them have), is one thing, and Norman Wiard, wielding the thunder of a great Joint Congressional Committee, is another. We decline to enter into any discussion of his foolish hypothesis, but we are forced to admit or deny the statements the committee have published for him.

(1.) It is stated that the conditions of rapid firing, which often occur in service, do not appear to have been realized in experimental firing, and therefore the destructive effects of heat have escaped the notice of experimenters. This is untrue. In 1863, comparative trials of banded and unbanded guns were made by direction of the Ordnance Department, and the effect of rapidity of firing was one of the specially designated objects of the investigation. These guns were, therefore, fired more rapidly than has ever been practicable in action, ranging from 93 to 140 rounds in two hours, and nothing whatever was developed to show that heating rendered them liable to burst. In the report of the siege of Charleston, General Turner states that after his officers and men had become experienced, the machinery of the carriages working smoothly, the 100-pounder could be fired once in 5 minutes, the 8-inch rifle once in 7 or 8 minutes, and the 10-inch rifle not oftener than once in 10 minutes. Eight rounds per hour is rapid firing for sea-coast guns. In experimental practice, the 100-pounder has been fired 20 rounds in 2 hours; the 8-inch rifle, 24 rounds in 2 hours 20 minutes; the 10-inch, 25 rounds in 2 hours 20 minutes. After the disaster at Fort Fisher, three 100-pounder rifles used in that action were fired 1,000 rounds each by direction of the Naval Investigating Committee, with a view of ascertaining, if possible, the cause of the bursting of the guns in that action. These guns all stood the test, and were fired during a large portion of the trial with greater rapidity than could possibly have been obtained in action, because no time was lost in sighting. Rapidity of firing has often been the subject of experiment where guns have been put to extreme proof.

(2.) The committee speak of the effects of the cooling of red-hot wrought-iron, of the strains inaugurated in the cooling of molten iron, &c., &c. As we see no connection between these hackneyed facts and the behavior of guns under fire, we omit to notice them further.

VI. The spontaneous rupture of guns is alluded to. This occurs sometimes in very large castings where certain grades of iron are used. So far as guns are concerned, it is liable to occur under bad management or carelessness whether the gun is cast solid or hollow. But every iron founder is well aware that there are some grades of iron too high for guns. It is not that which gives the highest tensile strength which is best suited for gun metal. The requisite material must have also a high degree or modulus of elasticity. The selection of the proper grades and qualities is a matter of extreme delicacy, and only the most perfect accuracy can insure the result. From the waste metal of every rough gun are taken test specimens, which are tested by the proper machinery as to their precise qualities, and any unusual deviation from the experimental standard subjects the gun from which it is taken to extra proof, or possibly even to rejection without trial. But it is satisfactory to know that such deviations seldom occur. When they do occur, it is not to be wondered at that the disturbance of the relations of molecular forces should manifest itself in spontaneous rupture. If the committee will obtain the passage of a law of Congress so altering the atomic constitution of elementary matter that it shall not deviate from standard behavior, and agree to enforce it, the Ordnance Department will no doubt consent to adopt the metal thus provided.

VII. We now come to the culminating point of the report:

"The fact that the ordnance officers of the Government find it necessary, at this late day, to return to the rudiments of their art, * * * shows a defect in the organizations of the Ordnance Departments calling for a remedy. The difficulty appears to have been two-fold; first, the ordnance officers, knowing their positions secure to them for life, have not felt the incentive to exertion and improvement which stimulates men not in the Government employ, and they have become attached to routine and to the traditions of their corps, jealous of innovation and new ideas, and slow to adopt improvements. An illustration of this is found in the fact, that the late war was fought with muzzle-loading guns (with the exception of carbines for cavalry), although a variety of excellent breech-loaders were urged upon the attention of the Government constantly, and the honor was reserved for Prussia, with a weapon inferior to many American inventions, to demonstrate the immeasurable superiority of breech-loading guns."

The charge of undue conservatism we shall not notice, further than to say, it is quite true with respect to the "improvements" urged by Mr. Wiard. That conservatism still exists, and we venture to prophesy that it will continue to exist when the humble writer of this notice gets to be Chief of Ordnance, at some dim distance in the future.

The "illustration" contains the same amount of falsification as many others. Primarily, the report speaks of the substitution of breech for muzzle loaders, as if it were a matter for instantaneous decision, involving no grave responsibilities. In the year 1860 no nation, and it is probably safe to say few individuals, thought of the general use of breech-loaders for infantry. Early in the war quite a number of infantry regiments were armed with the best breech-loaders known, and after a trial the advantages failed to appear. The first good breech or "magazine" loader offered was the Spencer. Numerous regiments were armed with it in the year 1864, perhaps earlier, and its merits in the hands of experienced troops were found to be decided. Every Spencer that could be obtained was taken by the Department for arming the cavalry, where its advantages were much more conspicuous than in the infantry. But the whole system of breech-loaders was so hedged in by patent rights, and these rights so powerfully backed up by political influence, that a general armament of the troops with these weapons was out of the question. Still the necessity for breech-loaders and their ultimate adoption was fully recognized by the Ordnance Department, and in 1865, the end of the war being felt to be near, vigorous steps were instantly taken for their supply, freed as much as possible from the insuperable clog of patent rights. The result has been the adoption of a breech-loader which the Department claims to be superior, by many degrees, to any in the world, and unhampered by the claims of patentees. Looking back with convictions now universally entertained, it is easy to ask, why were not these muskets adopted at the outset? *Going* back and looking forward we may reply, because no living man can predict any advantage for them. There was just one course to be followed in the premises — to select the most promising breech-loader, put it into the hands of the best regiments, and abide by the result. And this is precisely what was done. So far from Prussia setting us the example, Prussia had the benefit of our experience. Was anything heard in Europe before Kœniggratz of breech-loaders? Before that great day they were known and recognized here.

The report continues:

"In the second place, these officers, educated to a specialty and proud of their positions, come to look upon themselves as possessing all the knowledge extant upon the subject of ordnance, and regard citizen inventors and mechanics who offer improvements in arms, as ignorant and designing persons and pretentious innovators, who have no claim to consideration. Instead of encouraging the inventive talent of the country, these officers seem to have constantly discouraged it, and many complaints of improper and oppressive treatment have been laid before the Committee by persons who have sought to draw the attention of the proper authorities to what were supposed to be vital principles connected with their art."

It will be observed that Mr. Wiard speaks from bitter experience, and we could name others who probably have similar complaints to make.

"Another difficulty that has retarded progress in the science of ordnance has been the fact that prominent officers have been inventors of arms, and have possessed sufficient influence to secure the adoption and retention in service of their inventions, frequently without regard to the question of real merit, and to the prejudice of other and better devices brought forward by citizens or developed in other countries."

We are familiar with nearly every article used in the ordnance service—certainly with all important articles. A quarterly return of ordnance stores from some of our arsenals has been known to embrace some 12,000 to 13,000 different names of articles. We have spent some time in looking over the list also. As the result of our examination, we are unable to find any article upon which any ordnance officer is interested pecuniarily, in any way, by patent or royalty, directly or indirectly, unless, indeed, in some small item, unaccounted for, which will be stopped against the accounting officer's pay, when the Auditor gets hold of the vouchers. Gen. Rodman *did* have a patent on his method of casting guns, which he sold for a royalty to Chas. Knap, of Pittsburg, in 1847. The patent expired in 1861, was renewed for seven years, expiring again by limitation in 1868, and has not, I believe, been since renewed. As long ago as 1861, a hue and cry was raised against the Rodman patent, and when the petition for renewal was brought before Congress, a committee of investigation was appointed, consisting of Hons. Robert Dale Owen and Joseph Holt. The result was that Gen. Rodman's right to the patent was fully sustained and the renewal granted. We have known of a few instances where patents for ordnance stores have been taken out by ordnance officers, but the articles were not adopted by the Ordnance Board. The sentiment and practice of the officers of the corps is against patenting any improvement, excepting where the inventor has been put to great private expense for its perfection, though *the right* to do so is maintained.

VIII. We now come to some statements of "fact" which, with much falsehood, have a measure of truth in them, though, by their arrangement and juxtaposition, they are made to yield inferences as false as any others, showing that, although figures do not lie, men will sometimes lie tremendously about figures.

"Great diversity exists in the two branches of the service, respecting the arms adopted and the manner of proving, mounting and using the same. The calibers, models, chambers and ammunition of the navy guns are entirely unlike those in use in the army. For example, the navy 12-pounder boat howitzer has a caliber of 3.4 inches, while the army 12-pounder guns are of the calibers of 3, 3.2, 3.67 and 3.8 inches."

There is but one army 12-pounder now in service, and that is 4.62-inch caliber. Of the guns referred to, the only ones having the designated calibers are the 3-inch rifle, which, it is true, fires a shot weighing somewhere near 12 lb.—*i. e.*, $9\frac{1}{2}$ to $11\frac{1}{2}$ lb., and the 3.67-inch or 20-pounder Parrott. Surely no human being ever before thought of calling these guns 12-pounders. The 20-pounder Parrotts were seldom used except as siege guns, though they were not uncommon in the navy. There is a discarded "12-pounder," that is Mr. Wiard's own, though he does not mention it. Specimens can be seen at our arsenals, put up among the "nondescripts" to illustrate the freaks of inventive genius.

"The models of the two guns are entirely different, so that neither could be used on the carriage of the other. The system of sighting is also different. A gunner in one arm of the service, without special instruction, could not use a gun belonging to the other, one being graduated to seconds of time of the flight of the shot, the other to degrees of elevation."

We would also add for the benefit of the uninformed, that the navy guns are also unprovided with horses, and the sailors are without picks or shovels, and even caissons and battery wagons are wanting in the naval armament. Seriously—if it is possible to be serious—what do the committee mean by "using either gun on the carriage of the other." What kind of service, and on what element do boat-howitzers perform, or are field guns used? What does Jack want of a pendulum-hausse when sighting his gun among the waves, or a soldier of a time-scale on land?

"It is impossible to use navy ammunition in an army gun, or army ammunition in a naval gun."

That being the case we should by all means advise the navy to use their own ammunition exclusively, and we tender the same advice gratis to the army. Yet it is freely acknowledged by ordnance officers that the advantage of a uniform system *in the higher calibers* is a fair subject for discussion, to say the least, though the disastrous consequences of a lack of it is the veriest bugbear. Not pretending at all to "speak by the card" in this matter, I yet venture the surmise that army ordnance officers are more than willing: I know nothing about the navy opinion. The 20 and 15-inch guns are nearly conformable already.

IX. In presenting their conclusions the committee say that

(1.) "No more heavy guns should be purchased" at present.

(2.) "The Rodman system, while partially successful in smooth bores and small calibers, has so far failed in rifles of larger caliber as to show it to be unworthy of further confidence. * * * The principle of initial tension, which is the basis of the Rodman system, appears to be of doubtful utility, especially for rifled guns. This tension, it is admitted, gradually disappears with age, and is finally entirely lost."

We are curious to know, if the Rodman smooth bores are "partially" successful, what a complete success would be. We have before us a list of cannon, "burst or otherwise failures, in the national service" since 1860, published in the "Tribune" of April 5th, as we have reason to believe by Mr. Wiard. It is "prepared from reports and evidence before the Joint Committee on Ordnance." The recapitulation states that twelve 15-inch Rodmans were disabled. Looking over the "full catalogue" we do not find any specified, and we are morally certain there have never been any such disasters to specify. The recapitulation contains six 15-inch Rodmans self-burst; the catalogue specifies only three. As these burst before they were inspected, and, therefore, were not in the national service, they do not belong to the list. One 13-inch Rodman is specified as bursting at the 738th fire—a fair endurance for that caliber. Here, then, we have *one gun* out of the thousands built on the Rodman plan for smooth bores which has burst, and that after a fair endurance, and this upon the committee's own *ex parte* evidence. We hope we shall live to see a *perfectly* successful gun according to the idea of the committee.

The recapitulation specifies eleven 10-inch and 12-inch rifles on the Rodman plan as disabled. The catalogue specifies one 8-inch (the first one) at 80 rounds, and one 8-inch at 1,047 rounds—a very fine endurance—and one 12-inch at 470 rounds. This last gun was burst by the breaking and wedging of the shot in the bore, the pressure gauge showing a force of 135,000 lbs.! at the final discharge. Two other 12-inch rifles are "reported injured," but their injuries have never been heard of at the ordnance office. Nothing has yet transpired to discredit the Rodman rifles. Indeed their prospects are most hopeful. But few experiments have been made with them, and they are counted only as experimental guns. A sudden stop was put to all trials at the instigation of the committee, and the appropriation asked for to continue the experiments refused. This is the whole evidence upon which the Rodman system is pronounced a failure.

(3.) "Guns cast solid in the manner practiced in the navy under the direction of Admiral Dahlgren, while exhibiting satisfactory endurance as smooth bores, with small charges and hollow projectiles, have not the requisite strength for rifles of large caliber. This mode of casting seems to be defective in principle, as the tensions inaugurated in cooling have a tendency to aid the powder in rupturing the gun."

The Dahlgren guns need no defence. The wry faces made at them cannot be construed as an assault, and the only reply which can be made is to point to the record of the IX and XI in smooth bores.

A word or two about the Parrott system. It is useless to assert that these guns have proved perfectly successful. That, however, has little to do with their relative merits. The whole world is challenged to produce a large caliber rifle which has on the whole sustained so good a test. The English Armstrongs and Whitworths have shown no such average endurance, nor have the steel guns of England and Prussia. They are the only rifled guns in this country whose merits are known, and their record has on the whole been very good. Every experienced artillerist who has dealt with the 6.4, and 8 inch rifles can recall some instances of failure, but his confidence in them has been justified thousands of times where it has been shaken once. The unusual number of failures at Morris Island is ascribed to peculiar local causes. The fine and ever-drifting sand was blown perpetually into the muzzles of these guns, and with the lubricant and residuum of the powder formed a scale in the bore, which had to be removed with a steel chisel. Most of the failures occurred at the sand battery where this difficulty was greatest, while those having a marsh in front experienced scarcely an accident. Another alleged cause was the explosion of shells in the gun, generally by concussion, a disaster frequently occurring and which there seems to be no known method of preventing altogether. This is probably the chief obstacle to be overcome in rifle guns of large caliber, viz: a projectile that will leave the gun without breaking. The pressure gauge reveals the terrible danger of such a mischief, running up the pressure to 130,000 and 150,000 lbs., which is sure destruction to any gun which ever has been or ever will be made.

In reviewing the various systems of gun-making, the committee seem to have adopted the exhaustive process of argument. No guns made in Europe are of any value; of the guns made in this country neither the Rodman hollow cast, the Dahlgren solid cast, nor the Parrott banded guns, can be trusted. Wrought iron and steel are utterly condemned, and having exhausted every known or conceivable device, *with one exception*, we are categorically drawn to that exception. There is one system having no likeness to any other, and which the committee have indirectly countenanced, viz: Mr. Norman Wiard's. The record of Mr. Wiard's gun designed to obviate the destructive effects of heat is as brief as Cæsar's epigram—one gun, *one round*, many pieces.

But we must bring this paper to a close by one more revelation. Though morally certain of it, we do not assert that Mr. Wiard wrote that report. But we do assert that if he had been called upon to write one he would have written one substantially identical. In the supplement to the report of the Committee on the Conduct of the War, Vol. II, 38th Congress, 2d session, Senate Mis. Doc. No. 47, is a communication from Norman Wiard containing the same misrepresentations, groans, croakings and abuse of ordnance officers as appear in the committee's report, and in the same phraseology. Wiard's testimony contains the substance of the report, indeed the report is merely Wiard's testimony sand-papered. As Arrick wrote the other, why should not Wiard write this one? Lastly, we have it from high authority that at the direction of Senator Howard both Gen. Rodman and Admiral Dahlgren sat each a whole day to be pumped by this man, who put the questions, took down the answers, and probably "boiled down" the testimony as well as wrote the report.

As I have advanced no theories, but stated only matters of official record (except in one or two specified cases), the readers of the ECLECTIC will perhaps be able to form some notion of the unique character of this report. D.

STRENGTH OF SCREW SHAFTS.

A Paper "On the Calculation of the Stress in Propeller Shafts," read by W. J. Macquorn Rankine, C. E., LL. D., F. R. S., at the Institute of Naval Architects, March, 1869.

(1.) Through a long series of practical trials, extending over many years, it was ascertained by Lieutenant David Rankine (h. p. Rifle Brigade), and by the author of this paper, that the greatest stress which the wrought iron axles of very smooth-running railway carriages, traveling at speeds not exceeding twelve miles an hour, would safely bear, when made of the best materials and in the best way, was 9,000 lb. on the square inch (or about 6.3 kilos. on the sq. millimeter). Any defect in materials or workmanship, when exposed to that stress, was always found to cause the axle to give way in the end, though sometimes not until it had run for more than three years. The immediate breaking stress was not directly ascertained, but it is probable that the factor of safety was between five and six. A greater factor of safety, or, in other words, a smaller limit to the intensity of stress, is of course required when the motion is rougher than it was in those carriages.

(2.) According to the ordinary method of calculating the greatest stress in propeller shafts, the moment of the twisting action upon the shaft is alone taken into account; and when that method is applied to examples taken from actual steam vessels, results are obtained approaching very near to the limit already stated. For instance, 8,000 lb. to the square inch is a not uncommon value of the intensity of the stress in a propeller shaft, as calculated from the twisting action alone.

(3.) But the real intensity of the stress is greater still, for with the twisting action there is always combined more or less of a bending action, produced partly by the weight of the shaft and partly by its reaction when the vessel pitches and heaves with the waves. The object of the present paper is to give rules for calculating the total or resultant stress produced by the twisting and bending actions combined, and to illustrate them by an example.

(4.) TWISTING ACTION.—The *greatest twisting moment* is to be calculated from the indicated horses' power of the engines, as follows: Multiply the power by 33,000, in order to reduce it to foot-pounds per minute, and divide the product by 6.2832 times the number of revolutions of the shaft per min. The quotient will be the *mean twisting moment* in foot-pounds (for kilogrammeters the multiplier is 4,500 instead of 33,000). The *greatest twisting moment* is greater than the mean twisting moment in a ratio which may be estimated at about 1.6 for a single engine, 1.11 for a pair of engines with cranks at right angles, and 1.05 for three engines with cranks at equal angles.

When British measures are employed, the greatest twisting moment having been computed in foot-pounds, is to be multiplied by twelve to reduce it to inch-pounds.

To find the *greatest intensity of the stress produced by twisting*, multiply the greatest twisting moment by $\frac{16}{\pi}$ (= 5.1 nearly), and divide by the cube of the diameter of the shaft. In symbols, let M be the moment, d the diameter, and q the *twisting stress*, as it may be called. Then

$$q = \frac{5.1\,M}{d^3} \quad \ldots \ldots \quad (1)$$

(5.) BENDING ACTION.—The greatest stress produced on the particles of a horizontal cylindrical shaft by the bending action of its own weight is equivalent to the weight of a column of iron whose height is a third proportional to the diameter and the span between the bearings.

In symbols, let l be the span between the bearings (in inches if British measures are used); d the diameter; w the heaviness of iron (= .278 lb. per cubic in., or 7,690 kil. per cubic meter); p the greatest *bending stress*, as it may be called. Then

$$p = \frac{w\,l^2}{d} \quad \ldots \ldots \quad (2)$$

The *reaction* of the shaft produced by vertical oscillations, as in pitching and heaving, bears the same proportion to its weight that half the extent of the oscillations bears to the length of a pendulum which keeps time with them. Let m be that proportion; then the bending stress is increased to

$$p = (1 + m)\,\frac{w\,l^2}{d} \quad \ldots \quad (3)$$

In a vessel that follows the vertical heaving of the waves the value of m is nearly the sine of the wave slope—say, 0.25 in extreme cases, and 0.125 in ordinary cases.

(6). Resultant Stress.—The resultant stress due to the twisting stress q and the bending stress p combined, is found by a formula which has been demonstrated by writers on the internal equilibrium of elastic solids; that is to say,

$$s = \sqrt{\left(q^2 + \frac{p^2}{4}\right)} + \frac{p}{2}, \quad . \quad . \quad (4)$$

where s denotes the intensity of the resultant stress.

(7.) Numerical Example.—In the following example the results are not computed beyond four significant figures.

Indicated H. P.	5,500	
Multiply by..........	33,000	
Divide by ...... 6.2832)	181,500,000	ft.-lb per min.
Revo. per min ......54)	28,890,000	quot'nt nearly.
Mean twisting moment .	535,000	foot-pounds.
For a pair of engines multiply by........	1.11	
Greatest twisting mom't	593,850	foot-pounds.
Multiply by..........	12	
	7,126,200	inch-pounds.
Multiply by..........	5.1	
Diameter, 16½ in. ......)		
Diameter ³ ....4,492)	36,340,000	produet.
Twisting stress, q = ...	8,090	lb. on sq. in.
Span between bearings..	25 ft. = 300 in.	
Divide by diameter .... 16½)	90,000	square of span.
Third proportional.....	5,455	inches.
Multiply by weight of a cubic inch of iron ...	0.278 lb.	
Bending stress by weight alone	1,516 lb. on sq. in.	
× estimated value of 1 + m, say..........	1⅛	
Bending stress by weight and reaction = p =..	1,704 lb. on sq. in.	

Resultant Stress.

$s = \sqrt{\left(q^2 + \frac{p\,2}{4}\right)} + \frac{p}{2} =$ 8,987 lb. on the square inch, being practically equal to the greatest safe stress of 9,000 lb. on the sq. in., mentioned in sec. 1, as applicable to smoothly running railway axles at low speeds.

(8.) It seems very probable that if the method of calculation now described were applied to actual examples of propeller shafts, many instances would be found in which the resultant stress reaches, or even goes beyond, the utmost limits consistent with safety; and it is therefore laid before the Institution for their consideration, and for that of shipbuilders and marine engineers in general.

(9.) Rules for Designing Shafts.—The conditions which the diameter of a shaft ought to fulfill are expressed by the following equation, derived from equation 4:

$$s^2 - s\,p - q^2 = 0; \quad . \quad . \quad . \quad (5)$$

in which, for s, is to be put a safe working value of the resultant stress (say 8,000 lb. on the sq. in., or 5.6 kilos. on the sq. millimeter), and for p and q, their values in terms of M, l, w, and d, as given by equations 2 and 1 respectively. The equation then becomes of the *sixth order*, and it is to be solved so as to find d. This can be done by approximation only; and a convenient method of approximation is as follows: Assume for q an approximate value q^1, somewhat less than that of s (say, $q^1 = 0.9\,s$). Then calculate an approximate value d^1 of the diameter from equation 1, viz.,

$$d^1 = \left(\frac{5.1\,M}{q^1}\right)^{\frac{1}{3}} \quad . \quad . \quad . \quad . \quad (6)$$

Then calculate for p an approximate value p^1 from equation 3, viz.,

$$p^1 = (1 + m)\,\frac{w\,l^2}{d^1}\,; \quad . \quad . \quad . \quad (7)$$

and from the approximate value of p^1 calculate a second approximate value of q as follows:

$$q^{11} = \sqrt{(s^2 - s\,p^1)}. \quad . \quad . \quad . \quad (8)$$

Should this agree with the first approximate value q^1, the approximate diameter d^1 will answer; and should there be a difference, a second approximation d^{11} to the required diameter is to be computed as follows;

$$d^{11} = d^1 \left(\frac{q^1}{q^{11}}\right)^{\frac{1}{3}}. \quad . \quad . \quad . \quad (9)$$

When, as is usually the case, the difference $q^1 - q^{11}$ is small compared with q^1, the following formula for the second approximation is sufficiently near the truth:

$$d^{11} = d^1 \left\{ 1 + \frac{q^1 - q^{11}}{3\,q^1} \right\} \quad . \quad (10)$$

A third approximation might be found by repeating the process, but the second approximation will in general be found accurate enough for practical purposes.

Should q^{11} prove to be greater than q^1, the correction in equation 10 becomes negative; that is, the second approximation to the diameter is less than the first.

(10.) Example of the Rule.—$l = 300$ in. as before.

Twisting moment $M=$	7,126,200	in.-lb., as before.
Multiply by.........	5.1	
Divide by $q^1 = 7,200$)	36,340,000	product.
First approx., $d^{1\,3}=$..	5,047	
" " $d^1 =$..	17.15	inches.
Divide by $d^1 =$ ...17.15)	90,000	$= l^2$, as before.
	5,248	third proportional.
Mult. by $(1+m)\ w =$	.313	
First approx., $p^1=$..	1,643	lb. on the sq. in.
Intended resultant stress, $s =$	8,000	
Multiply by $s - p^1 =$	6,357	
Second approx. $q^{11\,2}=$	50,836,000	
" " $q^{11} =$	7,131	lb. on the sq. in.
First " $q^1 =$	7,200	
$q^1 - q^{11} =$	$-\,69$	

Second approximation to required diameter:

$$d^{11} = 17.15 \left\{ 1 \times \frac{69}{3 \times 7,200} \right\} = 17.21 \text{ in.}$$

ROLLING MILL GEARING.

The heaviest cog-wheels in the world—always excepting Mr. Isherwood's screw steamships—are to be found in iron rolling mills. Nothing at all resembling this gear is to be discovered in flour or cotton mills, or in any other situation on land where steam power is employed. Spur-wheels 18 ft. to 25 ft. in diameter, 24 in. wide on the face, and 8 in. or 9 in. pitch, are not uncommon; while pitches of 6 in. and widths of 18 in. and 20 in. may be met with in almost any little rolling mill we can enter. The quantity of gearing employed in driving an ordinary rail or forge train is even more remarkable than its dimensions. First, we have a tremendous spur-wheel on the engine shaft, working into a pinion on the fly-wheel shaft, which gears again into a spur-wheel, on the shaft of which is a square end to take the coupling-box and breaking-spindle to the rolls. We have in this arrangement three spur-wheels and six bearings, all of the largest and heaviest class; and this, be it observed, is rather a simple mill than otherwise. When a hammer, a shears and a second train have to be driven, we generally find as much gearing as would fill a good-sized modern dwelling-house, running at a high velocity, for the most part badly put to work, and therefore noisy and liable to accident. It is not too much to say, in fine, that at least one-half of the whole power developed is expended in keeping this gearing in motion; while its first cost represents one-half the capital invested in the plant of any iron mill.

It is worth while, under such circumstances, to consider whether gearing may or may not be dispensed with; and whether we can or cannot improve upon arrangements admittedly objectionable if tested by comparison with other mills. In dealing with the subject, we must first ascertain why gearing is used at all. This point is soon settled. The velocity at which ordinary trains run varies between 40 revolutions per minute for sheet mills and 100 revolutions per minute for bar or rail mills. Higher and lower velocities are met with, no doubt, but the two which we have named are those most usually adopted, and all that we shall say on this subject just now, will be sufficiently illustrated by cases afforded by those two speeds. Now the work to done in rolling iron is excessively variable, and it is therefore necessary to employ great fly-wheel power, in order to store up force at one time sufficient to carry the bar, rail or sheet through the rolls at another. Without going into mathematics, we may state here that the force afforded by any fly-wheel for overcoming the resistance offered to the rolls of a train varies as the square of the number of revolutions, the weights being the same. Thus, a fly running at 80 revolutions per minute would be practically four times as efficient as one similar in all respects and running at 40 revolutions. Therefore it has come to be looked on as an axiom by rolling mill engineers, that the fly-wheel cannot be run too fast. As a consequence, in old works we always find it put on a second-motion shaft, never on the engine shaft. In the endeavor to obtain high fly-wheel speed we find the first cause for the introduction of gearing in rolling mills.

The second reason lies in the fact that until a few years back, slow moving engines of great size were alone employed to drive sheet and rail trains. These engines had a long stroke, and ran at but eighteen or twenty revolutions per minute. This being too slow for any but blooming rolls, gearing became a necessity. The enormous dimensions usually imparted to rolling mill gearing is explained by the fact that it is exposed to many shocks and jerks which are peculiar to the work which it performs, and that for the most part it is roughly and cheaply made, and carelessly put together. We have, we believe, given in the foregoing paragraphs every valid reason which can be alleged in favor of the use of clumsy, heavy, costly gearing in rolling mills. It remains to be seen whether these reasons are or are not incontrovertible.

Taking the last phase of the question first, we may state that during the last few years better materials, better proportions, and superior workmanship have been introduced by many makers, such as Claridge, North & Co., and others, with a view to keep down the weight of mill gearing, and with much success, especially in Staffordshire; and it is beyond question that still more may be done in this direction. But it is quite in another way that we must look for radical improvement. We must begin at the fountain head, and instead of heavy, lumbering, slow working engines, resort to the use of machines making a fair number of revolutions without an excessive piston speed. A good deal has already been done in this direction, we are happy to say. At Woolwich arsenal the splendid bar mill is driven direct at some 60 revolutions per minute by a horizontal engine. In this case power is stored up in one of the finest fly-wheels in England, weighing 50 tons. The sheet train of the Warrington Wire Iron Co. is driven direct by an engine fitted with a 60-ton fly-wheel. These great weights are rendered necessary by the comparatively slow speed of the trains. When velocities of 100 revolutions are attained a 20-ton wheel will answer every purpose. As an illustration we may cite the Pendleton works, near Manchester, where a 16-in. rail mill is driven direct at 100 revolutions per minute, by a horizontal engine with a 26 in. cylinder and 4 ft. 6 in. stroke. This engine has been running constantly for the last fifteen years, with few or no repairs. The advantage of this system cannot be over-estimated. The cost of a great mass of heavy gearing is saved; the price of the engine is not nearly that of a larger and slower running machine; the chances of breakdowns are reduced to a minimum; and the expense of repairs, wear and tear, and lubrication is obviously very greatly diminished.

When, as in sheet mills, the rolls run too slowly to permit the engine to be coupled direct to them with advantage, the best plan will still be to use a small engine, running at some 70 or 80 revolutions per minute, and carrying on its shaft a spur-pinion gearing into a spur-wheel on a second-motion shaft driving the rolls direct; we thus retain a high velocity in the fly-wheel and a cheap engine, although some of the disadvantages connected with the use of gearing unavoidably remain.

The gearing at present usually employed in reversing mills consists of no fewer than five huge spur-wheels and pinions, besides the clutch-boxes. The entire arrangement is simply a barbarous relic of the past. Reversing mills should be driven by small, high-speed coupled engines, without fly-wheels, and fitted with a link motion. The first cost is not greater than that of the normal arrangement, while the waste of power and the chances of derangement are greatly reduced. Those who wish to realize what can be done in this direction, should see for themselves engines and mills designed by Mr. Ramsbottom for Crewe, and others manufactured by Messrs. Tennant, Walker & Co., of Leeds, for America.

The above is from the "Engineer." There are many mills in this country to which these criticisms apply. But the greater number of our *rail* mills have engines coupled directly to the trains—vertical engines, too, which take up the least room. And for work no heavier than rails our three high mill is a vast improvement on the reversing mill. Indeed, with proper lifting gear, it is probably better for the heaviest work, such as 15 in. beams. In some of the new English rail mills, two or even four trains are connected to a single engine by no end of cog-wheels.

We can copy the English practice with advantage in many cases; but in the matter of rail mills, our neighbors should study our practice, for instance at Reading, where they would see three 23 inch 3-high trains, driven each by its own direct vertical engine, at 60 to 80 revolutions; at Harrisburg, where a 40 in. by 60 in. direct vertical engine drives a 24 in. 3-high *steel* train, four rolls long, at 60 revolutions; and at Johnstown, where a similar engine, with a 60 ton fly-weel, drives, direct, a 21 in. puddle train five rolls long, and two squeezers.

THE BED OF THE ATLANTIC.—It has for some time been a question in the learned societies of England, as to the nature of a gelatinous substance formed at the bottom of the Atlantic, specimens of which have been brought up by sounding apparatus. Prof. Huxley has given it the name Bathybius. By some it is considered a gigantic Protozoön, which covers a vast area, miles in extent, forming a living mass over it. It would thus be an agglomeration of microscopic animalcules, probably possessing, like plants, the power of subsisting upon inorganic matter.

FAIRLIE'S LOCOMOTIVE CAR.

This is a long, eight-wheeled passenger car, resting at one end on an ordinary truck, and at the other on a locomotive truck. It is designed to run on rails laid upon common highways or upon ordinary railways. We compile the following description from "Engineering": The leading bogie, or truck, which has coupled wheels 4 ft. in diameter, is fitted with steam cylinders, and carries an upright steam boiler, and a platform for the driver and plenty of fuel space. The cylinders are inside, and are 8 in. in diameter, with 12 in. stroke. The boiler, which is of the "Field" class, stands on the platform of the truck midway between the two axles; the shell is continued downwards for about 16 in. below the fire-grate, so as to form an ashpit. The carrier frame is provided with a strap which completely encircles the base of the boiler, this strap being fitted with brass rubbing pieces on the inner side, so that the base of the boiler—which really forms a large bogie pin—can revolve freely within it to the extent of a quarter of a circle. At the hind end the carrier frame rests on the center of the trailing bogie, this latter being arranged so that it can swivel freely, and being provided with four ordinary carrying wheels, 2 ft. 6 in. in diameter. The carrier frame is made of four longitudinal frames, with cross frames and diagonals, the longitudinal frames being strengthened by truss rods, and the inside frames being connected for a portion of their length by plates at the top and bottom, so as to form a long shallow tank about 4 ft. wide by 12 in. deep. Under this arrangement the tank serves to materially stiffen the carrier frame, and at the same time the weight of the water is distributed over a considerable length of the latter.

The exhaust steam is led into the tank and made to traverse the whole length of the latter before being conducted to the chimney. In passing over the surface of the water a portion of the steam is, of course, condensed, whilst the remainder is discharged into the chimney without any objectionable noise. The chimney passes over the whole length of the carriage to the rear end; and we may here remark, by the way, that from experiments during the construction of some locomotives on the Northern Railway of France, having chimneys somewhat similarly arranged, it was proved that the action of the steam jet was fully as effective in chimneys so placed, as in those in the ordinary vertical position (!). Mr. Fairlie, however, places the chimneys of his steam carriages vertical, as usual in all cases, except when they are intended for working on a line laid along an ordinary road.

On the carrier platform is placed a carriage body, this latter being perfectly distinct from the carrier frame itself, and being merely a covering for the passengers, so that it can at any time be readily removed for repairs, and another bolted on in its stead. Instead, however, of removing the carriage body from the carrier frame, the latter may be readily detached from the leading bogie by simply taking out the bolts of the strap which embraces the base of the boiler, and the leading bogie—which may, in fact, be termed the engine—can then be attached to another carrier frame. When the leading bogie is detached, the front end of the carrier frame is supported on a pair of wheels which, by means of screws and a hand wheel with suitable gearing, can be lowered down so as to bear on the rails when desired. The ready means which are afforded for the detachment or separation of the various parts of Mr. Fairlie's steam carriage forms an important feature in his system, and one which will very greatly facilitate the execution of repairs. Thus, on a line where these carriages are employed, it will never be necessary to stop the running of an entire carriage to execute the repairs of one part, the replacement of a damaged engine, or carrier frame, by a duplicate kept in reserve, being the work of less than half an hour.

The construction of the carriage body is varied, by Mr. Fairlie, according to the nature of the traffic. For a light railway, constructed on a common road, and unprovided with regular stopping stations, (the carriage being intended to stop to pick up passengers like an ordinary omnibus,) the body is divided into two parts, for first-class (to seat 30) and second-class (to seat 50) respectively, the entrance to the former being in the rear of the vehicle, and that to the latter near the middle of the length of the carriage. A longitudinal gang-way runs the whole length. In both cases the steps are so arranged that passengers can readily mount into the vehicle from the road level. When the steam carriage is intended for running on a line provided with regular stations, Mr. Fairlie constructs the body with compartments and side doors in the ordinary way. Thus arranged the carriage is well adapted for working passenger traffic on branch lines or for metropolitan traffic.

In the construction of the vehicle, steel is used instead of iron in all parts where its employment is advantageous, and care has been taken, by properly proportioning the various details, to avoid all unnecessary weight. The calculated weight of the whole vehicle, without passengers, but with fuel and water for a 40 mile run, is under fourteen tons; whilst with 80 passengers the weight would only be 20 tons, of which rather more than half would rest on the wheels of the steam bogie. It will thus be seen that the ratio of unpaying to paying load is, when the carriage is fully loaded, only about $2\frac{1}{3}$ to 1, while, as about 55 per cent of the total weight is available for adhesion, the carriage would be readily able to mount gradients of 1 in 16, if sufficient cylinder power was provided. In the case of a steam carriage, designed for running on gradients 1 in 35 or 1 in 40, the following are the calculations of adhesion, etc.

On an incline of 1 in 35, the resistance due to gravity would be 64 lb. per ton; and if we take the frictional and other resistances, exclusive of gravity, at 20 lb. per ton —an ample allowance—we shall have the total resistances as follows:

Gravity, 20 tons, at 64 lb. per ton,		=	1,280
Friction, etc.,	20 "	=	400
Total, ...			1,680

Again, as about 55 per cent of the total weight rests on the wheels of the leading bogie, we should have

$$\frac{2240\times20\times55}{100}=24{,}640 \text{ lb.}$$

available for adhesion, an amount which, on an incline of 1 in 35, would be reduced to $24{,}640-\frac{24640}{35}=24{,}640-704=23{,}936$ lb.; and dividing 1,680 lb., the total resistance, by this number, we get $\frac{1680}{23936}=\frac{1}{14\ 8}$ as the co-efficient of adhesion required. In other words, so long as the adhesion exceeded, say $\frac{1}{14}$th of the weight on the driving wheels, the carriage would ascend an incline of 1 in 35.

On the other hand it will be found also, that the cylinder power is sufficient for taking the carriage up such an incline, the boiler being worked at a pressure of, say, 140 lb. per sq. in. Thus with 8 in. cylinders, 12 in. stroke, and 4 ft. wheels, the tractive force exerted for each pound of effective pressure on the pistons is 16 lb. To overcome the resistances amounting to 1,680 lb., as already calculated, the mean effective cylinder pressure would have to be 105 lb. per sq. in.

On a level road the total resistance of a steam carriage such as we are describing, running at a speed of 40 miles per hour, should not exceed 20 lb. per ton, or, taking the weight at 20 tons, 400 lb. in all. To overcome this resistance would require a mean effective pressure of 25 lb. per sq. in. on the pistons, and the power exerted would be $\frac{400\times5280\times40}{60\times33000}=42.6$ horse-power. On an incline of 1 in 100 the total resistance would be about $42\frac{1}{2}$ lb. per ton, or 850 lb. in all, corresponding to an effective pressure on the pistons of 53,125 lb. per sq. in., and to the development of 95.8, or say 96 horse-power at the same speed.

On a line with moderate gradients, say up to 1 in 60, and at speeds varying from 25 to 40 miles per hour, such a steam carriage as that we have described should be run with a consumption of about 6 lb. of coal per mile, and with a correspondingly small consumption of oil, tallow, etc. The expense for wages also would be very small, as the engine could be readily managed by one man, while the guard would have charge of the brake, and would be able to collect fares. Brake-blocks are to be applied to all the wheels; and the arrangement of brake-gear is such that the brakes can be applied either by the guard or driver independently.

Although the total wheel base of the carriage is 57 ft., yet the actual wheel base which has to be considered when estimating the capability of the vehicle for traversing curves, is that of each bogie, or 6 ft. only. With this base the carriage can be safely run round curves of two chains radius, at moderate speeds, while at a slow speed a curve of 35 ft. radius may be traversed. Thus, by placing circular curves of 35 or 40 feet radius at the terminal stations, the carriages can be run round, and the expense of turntables avoided.

We have hitherto spoken of Mr. Fairlie's steam carriage as running by itself only; but it will be evident from what we have said that it possesses ample power to draw, under ordinary circumstances, another carriage behind it. In the case of a railway laid on a public road, such speeds as 40 miles per hour would, of course, never be attempted, a speed of twelve or fifteen miles per hour being more nearly the maximum; and in such instances the boiler would possess ample power to supply the cylinders with steam at the full pressure admitted for, say three-fourths the stroke, and ample tractive power would thus be afforded for drawing another carriage, or trucks loaded with goods. Altogether Mr. Fairlie's plans are exceedingly well considered, and we feel sure that at the present moment — when light railways are the subject of much attention—they will be regarded with great interest.

INDEPENDENT TUBULAR BOILERS.

From the "Practical Mechanic's Journal."

The Seguin tube boiler applied to the early locomotive by the Stephenson's, and proved capable of such rapid and efficient generation of steam, gave almost at once an impulse to the use of tubular boilers of one sort or other for land and fixed engine use, which, however, has not been followed out, nor has progressed as steadily as might have been wished.

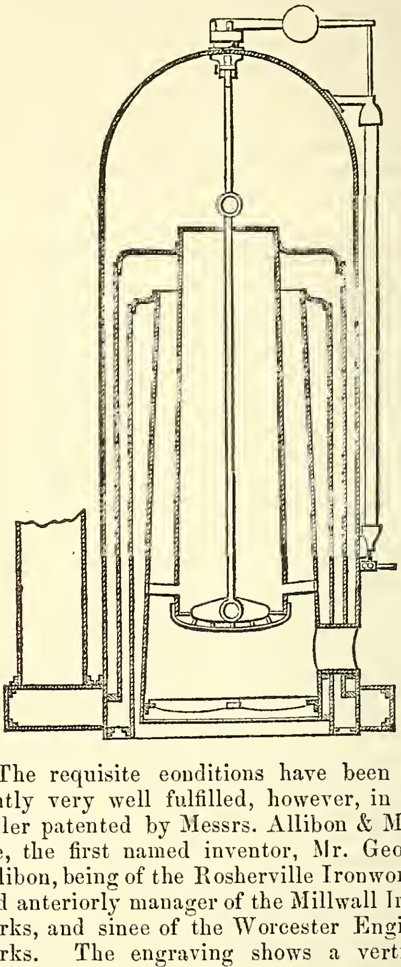
As long ago as about 1836 Messrs. Mather, Dickson & Co., of Liverpool, were amongst the first to adapt to fixed engines the locomotive boiler, pure and simple, but enlarged, and from the designs of Mr. John Grantham, C. E., the very large boilers, for that day, were constructed and fixed at Edgehill Station, for the supply of high-pressure steam to the fixed engines also constructed by them for working by rope traction the incline in the tunnel between there and Lime street. These boilers worked with economy and satisfaction for several years; we believe no objection was ever made to them but that of their considerable first cost. Many years ago, also, Messrs. Rennie employed for one or more engines in their works in London, a vertical boiler, consisting of a simple cylindric external shell, a drum fire-box inside, carrying above it a large number of vertical tubes, the gases from the whole of which were gathered into one central flue, which passed off directly from the top of the boiler. The water surface was necessarily below the top tube plate, and so a small length of the upper and cooler end of the tubes, and of the top tube plate, were exposed to contact with steam in place of water. This boiler, we were ourselves assured by the late Mr. George Rennie while examining it, had then for some time continued to give them steam at high pressure, with a consumption of mixed coal and coke equivalent to not more than $2\frac{1}{2}$ lbs. per hour per indicated horse-power.

This form of fixed tube boiler, of great simplicity, and as great cheapness as any tube boiler perhaps is susceptible of, had even to a rather greater degree than the horizontal-tubed locomotive boiler the advantage of permitting easy repairs. The misfortune of all fixed tube boilers, which, for land work, are required as one of their primary conditions to be worked for long periods and perhaps without a moment's cessation, is, that the surfaces of the tubes, whether these are exposed exteriorly or interiorly to the water contact, coat and fur over with earthy matter, deposited or collected, and concreted from the water at a rate that is injurious to them, though less so with boilers exposing broad, flat, or curved surfaces to the water. The small tube is practically at all temperatures so nearly the same diameter that scale formed does not easily crack off spontaneously, while it has a much better chance of doing so from broad surfaces, which are continually changing their shape with variations of pressure, and their dimensions with difference of temperature. Mere length in tube does not seem capable of letting it clear itself thus of scale. Besides hard accretional scale, most natural water deposits more or less loose mud or sediment. Now, the horizontal locomotive tube form of boiler may be so made for fixed or land use, that most of this shall keep away and deposit clear of the tubes. This advantage, however, is not secured by the simple vertical form of tube boiler above described, as constructed by Messrs. Rennie; for the loose sediment, as well as any that may detach itself from the tubes, falls down and lies amongst the tubes, on the lower tube plate, and gradually passes thence by ebullition and currents in the boiling water, down to the bottom of the water wards of the fire-box; and it is at all times an unhappy arrangement when the sediment tends to deposit finally about some of the hottest parts of the boiler plates.

Another form of fixed tubular boiler, known as Inglis' in the north of England, and, we believe, the subject of a patent, was in use at the Elswick Works, near Newcastle, about 1863, and when we saw it, appeared to have been working in a very satisfactory, and we learned, as we should have expected, in an economical manner. This boilers consists of two dome-topped cylindrical shells, of unequal diameter and height, connected together, above and below, by two cylindrical water flues, big enough for a middle-sized man to squeeze through. The larger cylinder contains the fire-box, and a smoke flue, rectangular in section, leading from the fire-box through the walls of both cylindrical shells, and into a cylindrical tube chamber in the center of the smaller cylinder, from whence a fasciculus of vertical tubes descends to the lower end or tube plate of the same cylinder. The whole boiler sits in brickwork, the ash-pit in front of the fire door being covered with a perforated cast-iron foot-plate.

Now most of the important conditions for tubular boilers are found here combined; every part, inside and outside, is as readily come-at-able as need be. There is ample circulation of the water, and a large surface both of fire-boxes and of tubes can be readily secured and well applied; moreover except as to the tubes themselves, scale has as a good chance of detaching itself here as in any other boiler of broad plates; there is ample room for the deposit of sediment, and by mud-hole doors can be made, so easily and so accessibly, that it can be periodically cleared out, if not removed even more frequently by mud cocks. It is also all pretty simple boiler-makers' work, both to make and to repair, and changes of dimension from hot to cold act systematically upon it, and tend little to rack its frame. It is, however, not a cheap boiler. When employed for uninterrupted service, the best mode of feeding it with water—and, indeed, this applies to every form of fixed tubular or lamellar boiler—would be to pass the feed water into a heating vessel of cylindrical form, placed in the horizontal flue, and so arranged that the sediment deposited in that could not enter the boiler, and should be easily removed from the vessel while the boiler continued at work.

A decided advance could be made thus upon the construction of multispaced fixed boilers, if we can abandon or reduce to the smallest extent tubes, and construct the boiler upon the lamellar principle instead; for then we shall substitute broad surfaces, which tend to keep clear from scale (under usual conditions), for small diametered tubes, which tend to clothe themselves with scale. This has been attempted in a multitude of forms—with flat water wards of one shape or another, as in Mr. Lamb's marine boilers; but such surfaces do not readily admit of the requisite strength for high-pressure steam, however admirably they may work under the conditions and moderate pressure of marine boilers.



The requisite conditions have been recently very well fulfilled, however, in the boiler patented by Messrs. Allibon & Manbre, the first named inventor, Mr. George Allibon, being of the Rosherville Ironworks, and anteriorly manager of the Millwall Ironworks, and since of the Worcester Engine-works. The engraving shows a vertical section of this boiler, the construction of which is so simple, that it will be understood almost without description by any one acquainted practically with boiler work. It consists of a vertical cylindrical shell (which may be of greater or less height to suit circumstances), containing four other shells nearly cylindrical, and so united that each alternate annular space is filled with water, while the other alternate ones afford, in a direction of movement up or down, passage for the gases of combustion of the fire, the fire-box for which is in the bottom of the cylindrical and internal shell, on their way to the chimney.

The advantages secured by this boiler are pretty evident; it is very simple in workmanship, and admits of great strength. Two of the cylindrical internal shells are exposed to compression on their convex surfaces by the steam or water, but these can be easily and well stayed up to those against the interior or concave surfaces of which the pressure acts. The parts are easily pulled out one from the other for examination or repair, and with extremely little boiler work, or unmaking and remaking of joints. There will be but little fast scale, but the loose deposits will require to be passed off at intervals with regularity. In our own judgment the four short tubes of water communication between the central cylinder would be best put somewhat higher up, and a sediment box of parallel contour with the rounded bottom of this cylinder placed within it, and suspended from above. If judiciously placed, and the feed water (from an external heater always) properly introduced and led first into that suspended vessel, we think almost all sediment would take place therein, and all the rest of the boiler remain nearly free. Two conjugate boilers of this sort obviously might be made, and fired from one fire-box in one of them, something as in Inglis' boiler, and probably with advantage as to consumption of fuel. This form of boiler might be made very suitably applicable to the use of liquid fuel, assuming, what has not yet been properly done, that that fuel is burnt as vapor, mixed with its equivalent of atmospheric air previously heated to a sufficient temperature by the waste or other heat.

We entertain but little doubt that these boilers will prove safe, economical in work, and, at the very least, as much so in repair, as any known form of multispaced boiler. In respect to its central cylinder this boiler bears some little similitude to Mr. Thompson's "pot boiler," exhibited in 1867 at Paris; none whatever, in its general design, which is greatly superior to that of the pot boiler.

Large Gas Holder.—Mr. Thomas F. Rowland, of New York, has built, for the works in Twentieth street, New York, a gas holder 170 ft. diameter, by 70 ft. high, in two 35 ft. sections.

TECHNICAL EDUCATION IN FRANCE.

We quote from "The Engineer" a translation of the scientific syllabus of the Paris Conservatoire. Scientific lectures are read by eminent *savants*, not only at the Conservatoire, but at the Sorbonne, Collège de France, Jardin des Plantes, &c., and this practice constitutes a most important feature in the French educational system.* In France secular tuition is either very cheap or entirely gratuitous, without any restriction as to age, sex, nationality, or religious opinions of the students; in fact, no questions are asked as the student enters the lecture-room, provided he behave decently.

CONSERVATOIRE IMPERIAL DES ARTS ET METIERS — PUBLIC AND GRATUITOUS COURSES OF LECTURES ON SCIENCE APPLIED TO THE USEFUL ARTS. 1868–1869.

Geometry, Practical.—M. Baron Ch. Dupin, Professor; M. Lausedet, Assistant. Programme: Theory of the principal curves employed in the drawing and construction of machinery; diagrams of parts serving to transform motion; toothed wheels; cams; eccentrics; articulations; escapements; counters; registering instruments.

Geometry, Descriptive.—M. de la Gournerie, Professor. Programme: Rules of linear perspective, and geometric constructions referring to it; effects of perspective; instruments of perspective; curved pictures; perspective of bas-reliefs; stage scenery; rapid perspective.

Practical Mechanics.—M. Tresca, Professor.—Programme: General principles of mechanics; definitions; effect of forces; mechanical work; principle of the conservation of work; means of developing and employing mechanical work; passive resistances; uses of machinery; composition of engines; description and theory of machinery used in industry.

Civil Constructions.—M. E. Trélat, Professor.—Programme: Materials, classified according to their uses, and to the æsthetic expression that they afford; theory of the elements of construction; foundations; vertical and horizontal walls; roofs.

Practical Physics.—M. E. Becquerel, Professor. Programme: Fundamental laws of general physics; the applications of heat; formation of vapors; use of their elastic force; sources of heat; warming and ventilation; molecular action; general laws of acoustics; fundamental laws of light; sources of light; construction of optical instruments.

Practical Chemistry.—M. E. Peligot, Professor. Programme: First part of the course, general phenomena of combination and decomposition; equivalents, nomenclature and symbols; natural history of simple non-metallic bodies, and of their principal combinations; air; water; mineral acids; ammonia; useful metals.

Manufacturing Chemistry.—M. Payen, Professor. Programme: Composition of vegetable matter, cellulose, preservation of timber and grains; starch, dextrine, glucose, gluten, Italian pastes;

---

* See Van Nostrand's Magazine, No. 2, page 116.

food; hygiene; sugar manufactures; alcohol, wine, beer, cider; paper; soap, gelatine; hydro-carbons, petroleum, lighting and warming gas.

Agricultural Chemistry.—M. Boussingault, Professor. Programme: Experimental demonstration of the process of testing and analyzing substances produced or utilized by agriculture; means of detecting adulteration.

Agriculture.—M. Moll, Professor. Programme: Exposition of the special rules of agricultural zootechnia; breeding, rearing, and employing horned cattle, pigs, poultry, horses.

Rural Works.—M. Mangon, Professor. Programme: Agricultural hydrology; drainage; manufacture of drain pipes; cleaning drains; desiccation (drainage); polders; colmatage (manure irrigation); ponds; fish culture; irrigation with pure or muddy water; legislation on water; plantation of forests; grass; sand-hills; forest industry.

Spinning and Weaving.—M. Alcan, Professor. Programme: First process in hand and machine weaving; plain, curled, and figured webs; openwork and stocking web; cleaning and mechanical preparations; sewing, embroidery, and ornament machines.

Dyeing and Printing.—These lectures are not commenced yet.

Political Economy and Industrial (Factories) Legislation.—M. Wolowski, Professor. Programme: Division of labor and co-operation; barter; money; law of germinal an xi. (of the French republic); trust money (credit); exchange; contractors and workmen; strikes; trade unions; association.

Industrial Economy and Statistics.—M. J. Burat, Professor. Programme: On production; on the forces employed by production; natural forces, work, capital; on the principles and economic laws regulating the industry of agriculture, manufactures, and trades; on the institutions which facilitate production; weights and measures, bills of exchange, and means of credit; means of communication, roads, canals, railways.

PRESERVING TIMBER.

An abstract of a paper read at the meeting of the Chemical Section of the Philosophical Society of Glasgow, by Mr. P. M. Moir.

This paper was specially written to explain the methods that have been and are now in use for the preservation of timber from decay by disease and exposure to the atmosphere, or destruction by marine worms and insects.

Timber when exposed to the action of the atmosphere is soon acted on by damp. This is especially noticeable in all timber fixed in the ground. The action commences at the parts immediately above the surface of the ground, where the fibrous portions of the wood are softened by the moisture, mould and decay being produced. These are indicative of a sort of slow combustion which is set up by the alternations of wet and dry. This kind of wasting away is termed wet rot. Another and very destructive form of decay is that which is known as dry rot. This goes on most rapidly where there is no circulation of air. It is believed by some persons to be caused by parasites; but by others it is believed that the parasites only appear after the decomposition has set in, and that they appear and live to consume the materials which by their accumulation might render the earth and air unsuited to the essential conditions of life and health. There is some probability that dry rot is a result of the felling of timber while it is full of sap, that is, between the end of spring and the beginning of autumn. Another familiar form of disease is that which is caused by the Termite or white ant. This creature's operations prove very destructive in India, Ceylon, Brazil, and most tropical countries. Its attacks are most ravenous on all wood buildings, railway sleepers, and bridges, even though the constructive material be lignum-vitæ, one of the hardest and most durable of woods.

When timber is used in marine structures the destructive agents are greater enemies than decay by dry or wet rot. There are two of them which are the best known among salt water destructive agents, and are very ruinous to all wood erections which are unprotected from their ravages either chemically or mechanically. They are the *Teredo navalis*, or ship-worm, and the *Limnoria terebrans*. The teredo is a long worm-shaped creature which perforates timber generally in the direction of the grain, but sometimes across the grain with many windings. When a knot is met with, or the shell of another teredo, the creature accommodates itself to circumstances by bending from its original course. In a fir pile taken from the old pier of Southend a worm was found two feet long and three-quarters of an inch in diameter. Some have been seen three and even four feet long, and one inch in diameter. The teredo grows very rapidly, and its ravages are often very terrible on ships, piles, &c. The teredo is not nearly so prevalent on the Scottish coasts as in the South of England and on the coasts of France and Holland where unprotected timber is readily destroyed.

The *Limnoria terebrans* is very abundant around the British shores. Its ravages were first particularly observed in the year 1810, by the late Mr. Robert Stevenson, engineer of the Bell-Rock Lighthouse. The limnoria very much resembles a wood-louse, and is about 1-6 inch in length. It is gregarious, and in situations favorable for the exercise of its habits it soon produces great effects on the wood to which it attaches itself. By boring in all directions it so disintegrates the wood as to allow the sea to wash away its surface, and thus layer after layer of the wood is riddled by the borer, and then abraded by the sea until the whole piece of timber attached is completely destroyed.

Various opinions have been entertained regarding the mode in which the limnoria perforates and destroys timber, but the opinion expressed by Dr Coldstream after very careful observation seems to be the most worthy of credence. He states that the animal effects its work by the use of its mandibles, and it seems that it is necessary that the hole should be filled with salt water. The distance bored is from one to two inches long, and as the hole increases in size the animal leaves its old workings and begins new ones.

All kinds of timber in the unprepared state, except greenheart, are readily devoured by the limnoria, if used in harbor works not exposed to the influence of fresh or river water. Greenheart is not molested by the animal at all, but every other kind of wood is attacked immediately that it is put into the sea, whether afloat or fixed, but more readily if fixed. The boring is generally limited to that portion which is between two-thirds flood and the bed of the sea or estuary. The rate at which the limnoria bores into wood in pure salt water is said to be about one inch in a twelve-month; but instances have occurred in which the destruction has been much more rapid. At Greenock, for instance, a pile twelve inches square was eaten through in seven years. The limnoria cannot live in fresh water, hence it is not found doing any damage in the Clyde higher than Port-Glasgow.

Greenheart timber in its natural state is the only wood now in use for harbor works that is proof against the attacks of marine creatures, and those of the white ant in tropical countries. There are two reasons why it enjoys this immunity from attack: first, there is its great hardness; and, secondly, there is the presence of a large quantity of essential oil. It is a very hard and durable wood, weighing about 75 lbs. to the cubic foot, and having a specific gravity of 1.089, so that it is a little heavier than water. It is brought from Demerara. Great care is required in working it, as it is very liable to split. In sawing it is necessary to have all the logs bound tightly with chains, failing which precaution the log would break up into splinters, and be very apt to injure the men working it.

The author then proceeded to discuss the various mechanical and chemical methods that have been employed to preserve timber from natural decay or from the destruction effected by living creatures. The mechanical methods are wholly employed for marine purposes, and are the oldest in use. One of these consists in covering piles, between high and low-water mark, with flat-headed iron nails, the heads being about one inch in diameter, and the nails being driven in so close that the heads touch, but do not overlap each other. This method is expensive, both on account of the materials employed and the time required in the operation; and besides this it is very inefficient, as the nails readily corrode, and leave room for the attacks of the living enemies. Another plan is to cover the piles or other submerged timbers with sheets of zinc or copper. This also is an efficient means of protection.

For the preservation of wood by means of chemical preparations, although many patents have been taken out, not more than six have been worked commercially. In all cases these patents were obtained for the use of solutions of certain chemical compounds as preservative agents. The names of the patentees and the most valuable compounds employed are shown in the following table:

Kyan - - -	1832	Chloride of mercury.
Margary - -	1837	Sulphate of copper.
Bethell - - -	1838	Creosote or pitch oil.
Bethell - - -	1848	
Burnett - -	1838	Chloride of zinc.
Burnett - -	1840	
Boucherie - -	1839	Pyrolignite of iron.
Boucherie - -	1846	Sulphate of copper.
Payne - - -	1841	Sulphate of iron.
Payne - - -	1846	Carbonate of soda.

The methods employed practically in working these patents were three in number, namely, steeping, vital suction, and pressing in close vessels. Kyan and Margary employed the first-mentioned method; Boucherie employed the second; and Payne, Burnett and Bethell employed the third, which was also latterly adopted by Boucherie. The first and third methods required that the timber should be seasoned and free from sap.

The author described each patented process at some length, mentioning how it is carried out, the advantages and disadvantages in each case, and the conditions under which it has any practical benefit. In no case did the evidence regarding the value of the process seem to equal that in favor of the creosoting process patented by Bethell, at all events if the timber is to be exposed to the weather or to be used in structural works which are subjected to the action of either fresh water or salt water.

Kyanising, or injecting corrosive sublimate (chloride of mercury) into timber, is very expensive if properly done; and besides this there is the fact that it is practically useless, inasmuch as it has been found that kyanised piles, after three years' immersion in the sea, did not contain a trace of the preservative compound.

Sulphate of copper, first suggested as a preservative agent by Margary, and afterwards employed largely by Boucherie, may be used to prevent dry rot in timber; but for piers, bridges, railway sleepers, and other structures which are exposed to the action of water, it has no practical value, as the water dissolves out the salt with great rapidity. Timber prepared with this salt, and used for marine purposes, is as readily destroyed by the teredo and the limnoria as unprepared timber.

In Payne's process solution of sulphate of iron is first absorbed into the wood, and afterwards carbonate of soda. Double decomposition ensues, and the practical result is the formation of oxide of iron, the deposition of which renders wood brittle, and does not prevent the attacks of either of the animals just named.

Of Sir William Burnett's chloride of zinc process the author could say nothing from personal experience. The essential part of the chemical action of the compound is the formation of an insoluble coagulum with the albumen of the wood. It is claimed for the Burnett process that it renders wood proof against the attacks of the white ants in India; and wood for in-door purposes is permanently improved by it.

Bethell's patent process for preserving timber by the use of creosote pitch oil is the only one which really accomplishes the object aimed at, although many patents for the use of oleaginous substances had been secured prior to the year 1838, with the same object in view. Creosote acts very powerfully in coagulating the albumen contained in the cells of the wood, and besides this it effectually preserves the fiber of the timber, and hence its value over all other so-called preservative agents.

The apparatus required in the creosoting process consists of an injecting cylinder, generally about six feet in diameter, and varying from 30 feet to 70 feet long, together with exhaust and pressure pumps, an oil tank, and the requisite piping connexions. It is not unusul to have both ends of the cylinders open, so that the timber may be entered at one end and removed at the other with the greatest facility, and to have them fitted with air-tight iron doors, which are removable at pleasure. When the cylinder is charged with timber, and the door or doors properly secured, the air is extracted by the air pump, both from the interior of the cylinder and from the pores of the wood. A vacuum being produced in the cylinder, the oil, which has been heated in the tank by steam pipes to a temperature of about 120° fahr., is allowed to rush in, and when the cylinder is full, the inlet pipe is shut and the pressure pumps are started to force the oil into the wood, the pressure being maintained at from 150 lbs. to 200 lbs. on the square inch until the wood has absorbed the required quantity of oil, which is learned by reference to an index gauge. For land purposes the amount of oil recommended is eight lbs. to the cubic foot of wood, and for marine purposes from 10 to 12 lbs. per cubic foot. In France, Belgium and Holland, the quantity used varies from 16 lbs. to 26 lbs. per cubic foot when the timber is intended for marine works. Beech wood has absorbed as much as 31 lbs. of oil per cubic foot, and when used for railway platforms or harbor works, it is doubtless the cheapest and most durable material that can be used.

Creosote (or pitch oil, as it is more commonly called in Scotland) is obtained in the distillation of coal tar, the other ingredients being ammoniacal liquor, crude naphtha, and the residual pitch. The coal tar of Scotch gas works generally yields about 25 per cent of oil which distils over at temperatures ranging from 400° to 700° fahr.; in England, however, the amount is only about 20 per cent. The author estimates the annual yield of pitch oil in Scotland at one million gallons, almost the whole of which is used for creosoting purposes. It is probable that creosote owes its valuable antiseptic property to the presence in it of from five to fourteen per cent of crude carbolic acid, but which could not be used by itself for outdoor purposes, as it is slightly soluble in water.

According to Dr. Letheby, creosote acts as a preservative agent in the following ways:

1st. It coagulates albuminous substances and gives stability to the constituents of the cambium and cellulose of the young wood.

2d. It absorbs and appropriates the oxygen which is within the pores of the wood, and so checks, or rather prevents the eremacausis of the ligneous tissue.

3d. It resinifies within the pores of the wood, and in this way shuts out both air and moisture.

4th. It acts as a positive poison to the lower forms of animal and vegetable life, and so protects the wood from the attacks of fungi, acari, and other parasites.

Since the creosoting process was first introduced in the year 1838 it has been extensively employed in Great Britain and Ireland; in all countries on the continent where creosote oil can be obtained—France, Holland, Belgium, Germany, Spain, Portugal, and Italy; and in India, Cape Colony, Brazil, and other tropical countries, to preserve timber from the attacks of the white ant. Wherever it has been properly carried out it has been completely successful.

Of late, many railway companies have discontinued the use of creosoted sleepers, not from any failure of the process, but from the wear and tear of the sleepers caused by the chairs cutting down into them and gradually rendering them useless. This mechanical injury to the sleepers would be greatly lessened were the base of the chair made broader. According to Mr. Deas, late engineer on the western section of the North British Railway, it will doubtless be less and less the practice of railway companies in this country, under the present financial depression, to creosote or otherwise preserve their sleepers, as the cost of the operation—6d. to 8d. per sleeper—is such a high proportion to the original cost of the sleeper, which is generally from 2s. 2d. to 2s. 6d. for each, while, owing to the cutting-down action of the chairs, the prepared sleeper becomes useless for permanent wear almost as soon as one unprepared.

For harbor works in Scotland the creosoting process has been largely used. At Leith, the west pier, consisting of 1,013 main piles, is entirely constructed of creosoted timber, and the extension of the east pier contains 312 main piles, also creosoted.—These erections were commenced in 1848, and finished in 1853, and at the present time they are as perfectly sound as the first day they were put down. The gates of the new dock now being constructed at that port are made of creosoted pine bound with greenheart timber, the quantity of oil used being ten lbs. per cubic foot. At Glasgow all the wooden wharves, with the exception of the steamboat quay, are constructed of creosoted pine, eight lbs. of oil to the cubic foot. The whole of the wharves at the Kingston Dock are built of creosoted wood, the same quantity of oil being used. At Port-Glasgow and Greenock timber prepared by the Bethell process is largely used, and the same is true of nearly every port in England. Much attention has been given to the creosoting process by the Belgian Government, and so satisfactory have the experiments been that no other process is used by that government. Very full and interesting accounts of the Belgian experiments upon the creosoting process have been prepared by M. L. Crepin, ingénieur des Ponts et Chaussées, especially in "Annales des Travaux Publics de Belgique," vol. xxi., 1864. M. Crepin affirms that wood retains all its former elasticity in the creosoted state, and acquires a density which it did not possess in the unprepared condition. M. A. Forestier, engineer-in-chief for the department of La Vendee, made a very minute and elaborate report for the Paris Exhibition of 1867 on the creosoting process and experiments made with it on timber used in both land and marine works in France; and in that country the process is also largely employed.

HOW STEREOTYPE-PLATES ARE MADE.

From the "American Artisan."

The surface of the types, set up as for printing, is first treated in the same manner as for electrotyping, except that it is oiled instead of being coated with black-lead. This being done, what is technically called a flask, simply a kind of rectangular frame is placed upon the chase. Plaster-of-Paris brought to the suitable consistency with water is then poured into the flask and upon the surface of the type locked up in the chase, and suffered to harden. This being done, the plaster mold thus formed is brought away from the chase, and consequently from the face of the type, by means of screws arranged at the corners of the flask. By this means the surface of the mold is kept intact from injury, which would occur if the movement of the flask in removing the plaster from the projecting faces of the type were irregular, or even very slightly in a lateral direction. When the mold has been completely detached from the face of the type it is fitted into a cast-iron pan, and both pan and mold are sunk to the bottom of a caldron of melted stereotype metal, which is somewhat different from, although closely resembling, ordinary type metal. This caldron is, of course, arranged over a suitable surface. The mold is suffered thus to remain in the molten metal until the heat of the latter has completely dissipated all the moisture of the mold, so that the metal penetrates without blowing into all the interstices of the mold. The mold being lifted from the caldron is filled with the molten metal, which on cooling constitutes the stereotype, requiring only the finishing operations of planing to thickness and the like to fit it for use in printing. These, being substantially the same as in the case of electrotypes, require no further description here. It should be mentioned, however, that previous to being thus finished, the plaster or material that may adhere to the plate must be removed therefrom by thorough washing, facilitated by the active application of a brush.

It is sometimes preferred that the plates should be cast in clay molds, instead of in those formed of plaster, the clay taking a better impression of low space work than the plaster, and having the additional advantage that it does not fill up the faces of the type like the plaster; this advantage obviating all necessity for cleaning the type after forming the mold, as is essential in the other case.

The material of which the clay molds are formed is common kaolin or potter's clay, mingled with powdered soapstone and properly tempered. Previous to use it is wrought and worked up with a solution of gum-arabic, and a little plaster is added.—Being brought to the requisite condition and consistency, it is spread upon the platen of a press, and the impression of the type or other surface is taken in the same way that the impression upon wax is taken in the preliminary part of the process of electrotyping. The clay thus impressed forms the mold that is to be, and is dried either in an oven contrived for the purpose, or by simply placing it upon the top of an ordinary furnace.—When the clay molds have become thoroughly dried, they are placed one over another and surrounded by metallic frames, which not only serve to close their sides, but also to keep them the requisite distance apart. When thus arranged the molten metal is poured into the spaces between, and on cooling forms the stereotype-plates in the same manner as if cast in the separate plaster molds. Plates may be cast more cheaply by the use of the clay-molds than by the others, and for all ordinary purposes the work is just as good. Where fine and sharp impressions are required, however, there is no mode of stereotyping that gives as good results as the plaster method.

As an addenda to the above description of the manner of making stereotypes practiced by Messrs. Lovejoy, Son & Co., we give a brief sketch of another process—the *papier-maché* process—employed in making the plates used in printing the large editions of some of the morning papers of this city, for which the simple forms of type alone would be wholly inadequate.

In carrying out this process a sheet of blotting paper of suitable size is covered on one side with a coating of paste prepared especially for the purpose, and upon this, and carefully smoothed with the hand, is placed a sheet of tissue-paper. This sheet it cut into pieces corresponding in size to the pages to be stereotyped, and each piece is coated on its face or tissue side with finely-powdered French chalk, applied with a soft brush. The surface of the page of type is sparingly coated with salad-oil, and the paper, face downward, is laid upon the surface of the type. This being done, a piece of damp linen is laid upon the back of the paper, and the paper is then beaten down upon the surface and into the type by means of what is known in the trade as a beating-brush, care being taken to bring the brush flatly down upon the paper at each stroke. When the paper has been well beaten into the type in this manner the cloth is removed, a piece of cartridge-paper is pasted upon the back of the paper matrix just formed, and the beating operation is repeated. This being done, the matrix, still upon the type, is subjected to the action of a press, and afterwards suffered to dry somewhat, which ordinarily requires but a few minutes, after which the matrix is gently lifted and separated from the type.

In casting the plate the matrix is fitted in what is termed a mold, and the metal is poured in, and, filling the mold, on cooling forms the plate, which, if all the various operations of the process have been properly carried on, easily separates from the matrix, and by a few finishing touches is rendered fit for use.

This *papier-maché* process has the advantages of cheapness and quickness in making the plates, and the latter are about equal in quality to those made in the clay molds above described. It is found, however, that the beating of the paper upon the type destroys, in time, the hair lines upon the latter, and thus impairs their value. Another objection to this plan lies in the deterioration of the type-metal, which is found to occur, for some unexplained reason, when the metal is cast upon the paper material of the matrix.

COMMUNICATION BETWEEN ENGLAND AND FRANCE.

From "Engineering."

The prospects, engineering and commercial, of a tunnel beneath the Dover straits, the possibility of constructing such a work, and the chances of a profitable issue if it were ever completed, are at last in a fair way of being thoroughly investigated and decided, so far as it is possible for able engineering foresight to decide them. It is at least a satisfaction to know that the idlers who, with scarcely capacity to lay a water main, treat the construction of twenty-five miles of submarine tunnel as a mere trifle, will perforce cease from troubling with their visionary executive and revenue estimates when a sound opinion has been given on the matter. It is but just, however, to all these schemers to admit, that their perseverance has done something to impress the fact that the present means of communication with the Continent are eminently inefficient and unsatisfactory.

It *may* be, for the limits of possibility cannot be set, that the next generation will see the completion of a railway ligature joining France and England, and that the traffic will have increased so enormously as to pay the high dividends which alone could remunerate the venturous capitalists for their precarious investment. But this, as yet, is beyond the province of sober belief; and there is no reason to imagine, as the advocates of the Channel Tunnel would have us imagine, that passengers would travel in millions beneath the bed of the sea, instead of in thousands on its surface, or that, to the popular mind, an hour of mental agony in a tunnel would be welcomed in exchange for sixty minutes' physical discomfort on the surface. Assuming, however, for a moment that such a scheme has been pronounced feasible, and that the twelve millions or so have been raised for the work, England and the Continent would have to wait patiently for, perhaps, a quarter of a century till the tunnel was completed; so that, at least pending the construction of this great undertaking, we must look for some efficient, if only temporary, means for superseding the present miserable accommodation.

Such a plan is offered by Mr. John Fowler, and the other engineers associated with him, in his English and Continental Intercommunication scheme, deposited last Session, and postponed till next year, for the adjustment of preliminary arrangements, and for the further consideration of the project. It is, indeed, no matter for regret that, publicly, the bill will lie dormant till next Session, for the interval will give time for present opposition to be converted in future co-operation, while the agitation of the permanent communication advocates will urge forward the undertaking.

The route chosen for the crossing is from Dover to Audrecelles, which latter port offers far greater advantages than does the coast at Calais. A shorter course—only 23 miles from dock to dock—deeper water, an absence of shifting sand-banks, and a complete protection from the easterly and north-easterly winds under the lee of Cape Gris-nez, whose lighthouse would direct the course, are among the obvious advantages of the new proposed route. The construction of a few miles of railway from Audrecelles to Wimereux, will save the journey from Calais to the latter station, and shorten the distance to Paris by fourteen miles, although of course travelers to Brussels and towards the north would suffer this disadvantage now incurred by those who have Paris for their destination. As the former class of travelers are, if anything, a little more numerous than the latter, it follows that the traffic of the railway would be increased by the change of landing places, even if the increased facilities of crossing did not stimulate travel. But of this there can be no doubt, although not in the extravagant degree claimed by the tunnel advocates, who must look forward to an unceasing stream of about 250 passengers per hour throughout the year, and an increase of goods' traffic in like degree, to earn a revenue sufficient to pay their dividends and maintenance expenses. This *may* come in the future, created by the submarine link, but so far as we can see there is not a single advantage, claimed for the permanent communication, which is not possessed by the ferry, whilst the latter scheme is, on the other hand, free from the objections fatal to the tunnel.

A moderate capital, easily obtained, would suffice in a short time to establish a perfectly efficient and satisfactory service, that would so far encourage and increase traffic as to produce a revenue representing a large return upon the outlay. The railway companies, both English and Continental, would obtain corresponding advantages with the increasing traffic promoted by the new service, and above all, of far more importance than the new comfort derived by passengers, a satisfactory means of transporting merchandize would be gained, and the delays and injuries to which goods are now constantly exposed would be avoided. Concentrating at Audrecelles from all parts of Europe, the goods' wagons would be transported to the opposite dock to the benefit of the Chatham and Dover and of the South-Eastern Railways, which would necessarily secure through the ferry the bulk of the merchandize that is now exported for the various shipping places of the Continent to the English ports.

Offering all these advantages, we cannot doubt that the English and Continental Intercommunication bill will be freely passed next Session, and that the works will be commenced without delay. The public and the railway companies are alike interested in its completion, and though it *may* have in its turn to give place to a permanent communication, it will have probably a half century of good service without competition, and it would afterwards doubtless be leased, and kept in working order by the tunnel company, in the event of any contingency, to which that great work, after its completion, might in the course of nature be liable.

The Pennsylvania Ironworks, Chester, Pa., have closed a contract with parties in New York for the building of a number of iron steam-colliers for the coasting trade, having a carrying capacity of about 600 tons. They are only the pioneer vessels of a projected large fleet for cheaply transporting coal from the most convenient points of shipment to consumers. Some railway companies are interested in the enterprise.

THE INDICATOR.

PRACTICAL DIRECTIONS FOR APPLYING AND TAKING CARE OF THE INSTRUMENT.

From Porter's "Richard's Steam Indicator."

I.

Of Attaching the Indicator.—When it is practicable, diagrams should be taken from each end of the cylinder. The assumption commonly made, that if the valves are set equal, the diagram from one end will be like that from the other, will be shown by this instrument to be erroneous. This is owing to the difference in the speed of the piston at the opposite ends of the cylinder, which is, at the outer end of a direct-acting engine, from 35 per cent to 66 per cent greater than at the crank-end, the difference varying according to the degree of angular vibration of the connecting-rod. In side-lever or beam-engines, these proportions are reversed, and the speed of the piston is greater at the upper end of the cylinder. Often, also, there is a difference in the lengths of the thoroughfares, and in the lead, or amount of opening, or the point closing; and many times the valves are supposed to be correctly set, when this Indicator will show that they are not. These and many other causes, will make a difference in the diagrams obtained from the opposite sides of the piston.

One use of the Indicator is in fact to show whether or not the diagrams from opposite ends of the cylinder *are* alike.

Pipes to be Avoided.—The Indicator should be fixed close to the cylinder, especially on engines working at high speeds. If pipes must be used, they should not be smaller than half an inch in diameter, and five-eighths in the bends, and as short and direct as possible. Any engineer can satisfy himself with this instrument, that each inch of pipe occasions a perceptible fall of pressure between the engine and the Indicator, varying according to its size and number of bends and the speed of the piston. Diagrams have been known to show, from this cause alone, 40 per cent less pressure than was actually in the cylinder. Probably the diagrams taken from engines, generally show in nine cases out of ten, the lead or the pressure or both, untruly, from the incorrect manner in which the instrument is attached.

Where to Connect the Indicator.—On vertical cylinders, for the upper end, the

Indicator cock is usually screwed into the cover. Sometimes it is attached where the oil-cup is set, this being removed for the purpose. For the lower end, it is necessary to drill into the side of the cylinder, at a convenient point in the space between the cylinder bottom and the piston, when on the center, and screw in a short bent pipe, with a socket on the end to receive the Indicator cock. This Indicator can be used in a horizontal position, but it will be found much more convenient to put in a bent pipe, and set it vertical. Sometimes it will be necessary to drill in the side of the cylinder at the upper end also, especially in double cylinder engines having parallel motions, when the Indicator cannot generally be set on the covers. Care must be taken that the piston does not cover the hole when on the center. No putty is necessary to make these small joints, and it should never be used, as it is liable to clog the instrument. If the screw fits loosely, a few threads of cotton wound round the stem will prevent the escape of steam.

On horizontal engines, the best place for the Indicator is on the top or upper side, at each end; if it cannot be placed there, bent pipes may be screwed into the covers or into the side of the cylinder. In other respects follow the directions given for vertical engines. The Indicator should never be set to communicate with the thoroughfares. The current of steam past the end of the pipe or the hole reduces the pressure in the instrument, and the diagram given is utterly worthless, as any engineer can readily ascertain by making the experiment.

The stop-cock being screwed firmly in its place, screw the Indicator down to its seat, turning it to the most convenient position, and make it fast by turning the coupling; then move the guiding-pulleys to their proper position to receive the cord, and the instrument is in readiness for use.

II.

Of Giving Motion to the Paper.—*The Drum the best Means.*—The revolution of a drum is probably the most correct as well as convenient method of giving motion to the paper. It may be supposed that a flat slide, worked by positive means, would have a perfectly accurate motion; but, in fact, at high velocities, where alone any trouble is met with, the difficulties involved in its use are more troublesome than those presented by the cylinder. In most cases the connecting-rod must necessarily be somewhat long; it must not tremble, or the line on the paper will be tremulous, and the weight required for stiffness, joined to the weight of the slide, causes a momentum, which, if the rod is worked by a vibrating arm, will give to the paper, on each center, a motion opposite to that of the piston of the engine; and precisely at these points it is of the greatest consequence that the two motions shall coincide.

In the use of the cylinder at any speed, the question of obtaining a positive motion, if there is no elasticity in the cord or the parts to which it is connected, is simply one of proportion between the momentum of the revolving parts and the strength of the spring by which this is resisted. In this Indicator these parts are made as light as possible, consistently with other requirements, and the spring is of such strength that they may be reciprocated from 250 to 300 times per minute, without any increase in the length of the diagram, and of course, therefore, without any error in the motion. There is no difference in the construction of these Indicators in this respect, it being intended that every instrument shall be applicable to any engine.

From what Points to derive the Motion.—This may be taken from any part of the engine which has a motion coincident with that of the piston. For a beam-engine a point on the beam, or beam-center, or on the parallel-motion rods where these are employed, will give the proper motion; but care must be taken that the cord be led off in the right direction—a requirement which is sometimes overlooked; afterwards its direction of motion may be changed as required.

In some cases it is most convenient to take the motion from a point on the end of the revolving shaft; this is frequetly the case on horizontal engines, working at high speeds, because then the motion does not need to be reduced. Exact accuracy cannot be got in this way, however, without employing a moving slide and connecting it with the pin in the end of the shaft by a rod or cord of such length that its angular vibration shall be the same as that of the connecting-rod. This will be found generally a troublesome matter, and the engineer will probably prefer, in most cases, to disregard the error resulting from its omission—which is, that the motion of the paper will be more nearly equal at the two ends of the stroke, being slower than that of the piston at the one end, and faster at the other. The crank or pin from which the cord receives its motion must be on its center, relatively to the direction of the cord, whatever that direction may be, precisely when the crank of the engine is on *its* center. If this requirement is not carefully attended to, the diagram will be worthless. Generally, on horizontal engines, the motion of the paper is taken from the cross-head. In an engine-room, a strip of deal board may be suspended from the ceiling in such a manner as to permit it to swing backward and forward, edgeways, by the side of the guides, and motion may be given to it by a pin secured firmly to the cross-head, and projecting through a slot in the board, in which it should fit nicely to prevent lost time on the centers. The board must hang plumb when the piston is in the middle of its stroke. The cord may be connected to this strip of board at a point sufficiently near to its point of suspension to give the required reduction of motion for the paper, and must be led off in a horizontal direction, and then over one or more pulleys in any required direction to the Indicator. At high speeds, however, pulleys should be avoided. On portable engines, the motion may be obtained in the manner just described, the lever swinging from a pin supported in a standard about two feet in height, set on one of the guide-bars.

On locomotives having outside connexions, the motion must be taken from the cross-head. It is indisputably necessary to use only a short direct cord, free from elasticity, and connected to a point, the motion of which is reduced from that of the cross-head by positive means. Care must be taken also to so proportion the parts employed for this purpose, that the point at which the cord is connected shall have a positive motion without any fling, a matter not by any means free from difficulty at 250 revolutions per minute. A rock-shaft, turning in bushings, supported by two angle iron standards precisely over the mid-position of that point of the cross-head from which the motion is derived, affords perhaps the best means of reducing the motion. A long-arm is worked by the cross-head, and a short-arm gives motion to the cord. The short-arm must be keyed in such a position that when the piston is in the middle of its stroke it will stand at right angles with the direction of the cord, whatever that may be.—The direction of the cord may form any necessary angle with the horizontal line, but must be at right angles with the rock-shaft. On locomotives having inside connexions, and a single pair of driving-wheels, where it is practicable, it will be found the better way to take the motion from a pin set in the end of the shaft, and to communicate it by a connecting-rod to a point convenient for attaching the cord. The parts should be all substantially made; the momentum of the connecting-rod will be perfectly resisted by the pin. On oscillating engines, the motion may be taken from the brasses at the end of the piston-rod. If the stroke is long, it is sometimes difficult to reduce this motion to that required for the paper, and in such cases it is necessary to take the motion from an eccentric on the main shaft, to a point as near as possible to the trunnion, and thence to communicate it to the Indicator. In all these connexions, it is of the first consequence that there be *no* lost time which will require to be made up on every center, and will thus cause the paper to stand still while the piston is moving.

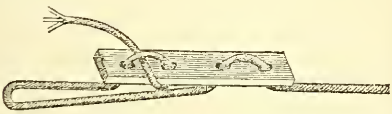
Pulleys of different diameters on the same spindle have been often used as a means of reducing the motion from that of the cross-head, but we do not recommend them; at high speeds it is very difficult to make them answer. The experience of the careful operator will teach him to guard against the various causes of error here mentioned, and others which will arise in the great diversity of situations in which the Indicator is used, and the effects of which are the more mischievous, because often the diagram itself furnishes no means of detecting them. The mathematician will perceive that *perfect* accuracy of motion is attained by only a very few of the methods here suggested. Most of them are only approximately accurate, but they are the best which can be readily employed, and the errors which they involve are too slight to be of practical moment. For the professional engineer, of course, directions are unnecessary.

III.

How to take a Diagram.—*To fix the Paper.*—Take the outer cylinder off from the instrument, secure the lower edge of the paper, near the corner, by one spring, then bend the paper round the cylinder, and insert the other corner between the springs. The paper should be long enough to let each end project at least half an inch between the springs. Take the two projecting ends with the thumb and finger, and draw the paper down, taking care that it lies quite smooth and tight, and that the corners come fairly together, and replace the cylinder. The spring used on this Indicator for holding the paper will be found preferable to the hinged clamp. A little practice, with attention to the above directions, will enable any one to fix the paper readily.

The marking-point should be fine and smooth, so as to draw a fine line, but not cut the paper. It may be made of a brass wire; the best material is gun-metal, which keeps sharp for a long time, and the line made by it is very durable. Lines drawn by German silver points are liable to fade. A large-sized common pin, a little blunted, answers for a marking-point very well indeed; a small file and bit of emery cloth used occasionally will keep the point in order.

To Connect the Cord.—The Indicator having been attached, and the correct motion obtained for the drum, and the paper fixed, the next thing is to see that the cord is of the proper length to bring the diagram in its right place on the paper—that is, midway, between the springs which hold the paper on the drum. In order to connect and disconnect readily, the short cord on the Indicator is furnished with a hook, and at the end of the cord coming from the engine, a running loop may be rove in a thin strip of metal, in the manner shown in the following cut,



so that it can be readily adjusted to the proper length, and taken up from time to time, as it may become stretched by use. On high-speed engines, it is as well, instead of using this, to adjust the cord and take up the stretching, as it takes place, by tying knots in the cord. If the cord becomes wet and shrinks, the knots may need to be untied, but this rarely happens. The length of the diagram drawn at high-speeds should not exceed four and a half inches, to allow changes in the length of the cord to take place to some extent, without causing the drum to revolve to the limit of its motion in either direction. On the other hand, the diagram should never be drawn shorter than is necessary for this purpose.

To take the Diagram.—Everything being in readiness, turn the handle of the stop-cock to a vertical position, and let the piston of the Indicator play for a few moments, while the instrument become warmed. Then turn the handle horizontally to the piston in which the communication is opened between the under side of the piston and the atmosphere, hook on the cord and draw the atmospheric line. Then turn the handle back to its vertical position and take the diagram. When the handle stands vertical, the communication with the cylinder is wide open, and care should be observed that it does stand in that position whenever a diagram is taken, so that this communication shall not be in the least obstructed. The instrument is provided with a stop, to prevent the marking point from tearing the paper. The arm is to be pressed firmly up to this stop. If the line drawn is faint, the point must be screwed up and back if the line is too heavy. The elasticity of the parallel arms gives the light pressure required on the paper. As the hand of the operator cannot follow the motions of an oscillating cylinder, it is necessary that the point be held in contact with the paper by a light spring, and instruments to be used on engines of this class are furnished with an attachment for this purpose. Diagrams should not be taken from an engine until some time after starting, so that the water condensed in warming the cylinder, &c., shall have passed away. Water in the cylinder in excess always distorts the diagram, and sometimes into very singular forms. The drip-cocks should be shut when diagrams are being taken. As soon as the diagram is taken, unhook the cord; the paper cylinder should not be kept in motion unnecessarily, it only wears out the spring, especially at high velocities. Then remove the paper, and minute on the back of it at once as many of the following particulars as you have the means of ascertaining, viz:

The date of taking the diagram and scale of the Indicator.

The engine from which the diagram is taken, which end, and which engine, if one of a pair.

The length of the stroke, the diameter of the cylinder, and the number of double strokes per minute.

The size of the ports, the kind of valve employed, the lap and lead of the valve, and the exhaust lead.

The amount which the waste-room, in clearance and thoroughfares, adds to the length of the cylinder.

The pressure of steam in the boiler, the diameter and length of the pipe, the size and position of the throttle (if any), and the point of cut-off.

On a locomotive, the diameter of the driving wheels, and the size of the blast orifice, the weight of the train, and the gradient, or curve.

On a condensing-engine, the vacuum by the guage, the kind of condenser employed, the quantity of water used for one stroke of the engine, its temperature, and that of the discharge, the size of the air-pump and length of its stroke, whether single or double-acting, and, if driven independently of the engine, the number of its strokes per minute, and the height of the barometer.

The description of boiler used, the temperature of feed-water, the consumption of fuel and of water per hour, and whether the boilers, pipes and engine are protected from loss of heat by radiation, and if so to what extent.

In addition to these, there are often special circumstances which should be noted.

IV.

How to Keep the Indicator in Order.—The Indicator will not continue to work well, unless it is kept in good order. When used, it generally becomes full of water, which will rust and thus weaken the spring, and the steam often contains impurities and grit, a portion of which is lodged in it. After the Indicator has been used, and before putting it up, unscrew the cover of the cylinder case, and draw off the upper ferule, with the pencil movement and the piston and spring attached, empty the water from the cylinder case, carefully clean and dry all the parts, and replace them, lubricating the cylinder with a few drops of oil which is entirely free from gum. The cylinder is not to be removed from the case under any circumstances; the operation above directed gives complete access to it.

Sometimes the surfaces of the piston and cylinder become scratched or roughened by impurities in the steam, a fact which will be detected at once in the diagram by the unsteadiness of the line. If this shows the existence of any obstruction to the perfectly free action of the Indicator, take the instrument apart, as for cleaning, and remove the spring, then replace the piston in the cylinder after cleaning and lubricating them; screw on the cover to guide the stem, and rub the piston up and down in the cylinder, at the same time revolving the stem between the thumb and finger. The surfaces will quickly wear each other smooth; no grinding or polishing material should be used, but the piston should be taken out once or twice during the operation, and the surfaces cleaned. The piston, if dry, ought to drop perfectly free from every position. Before replacing, lift the levers and let them fall, to see if their action also is entirely free.—Then replace everything, taking care to screw the heads of the spring firmly up to the piston and cover. The paper cylinder requires to be lubricated occasionally with a drop or two of pure oil applied at the end of the arbor, also the leading pulleys and the joints of the pencil movement.

V.

How to Change the Springs.—Unscrew the coupling from the end of the piston-stem, the cover from the cylinder-case, and the spring from the piston and cover; introduce the new spring, and screw all up firmly again.

The length of the springs for the different scales are so proportioned to each other, that the pencil will always come to the proper position for drawing the atmospheric line. In putting in the spring No. 1, the head from which the barrel projects to stop the compression of the spring should be screwed to the cover and not to the piston. Be careful that the heads are screwed up firmly to the piston and cover.

The spring which gives reaction to the paper cylinder is liable to break after considerable use, especially on engines running at high-speeds, for which reason this cylinder should never be left to run unnecessarily. When breakage occurs a new spring can be readily substituted, as follows: set the Indicator on the engine, if there is no other convenient means for holding it firmly, and remove the cover of the spring case and the broken spring. Then hook the new spring on to the hook projecting from the ferule on the arbor, coil it into the case, and hook the end on the rim; see that it is coiled in the same direction with the cord. If the string has not sufficient strength to keep the cord quite tight, another coil must be given to it, but it should not be coiled any tighter than is necessary for this purpose.

Prices of Springs and Metallic Paper.—The springs and metallic paper may be procured from any parties who sell these Indicators. The springs will be sent free by post to any address, on receipt of the price in stamps.

	Prices. £	s.	d.
Piston springs, with boxwood scales, each.	0	10	0
Paper cylinder springs	0	1	6
Quire of metallic paper, cut into 360 diagram sheets	0	4	0

Indicators for special purposes, or containing special modifications, will be made on application.

THE CENTRIFUGAL FORCE OF BELTS.

By W. J. Macquorn Rankine, C.E., LL.D., F.R.S.

From "The Engineer."

OBJECT OF THIS COMMUNICATION.—It is well known, through practical experience, that a belt for communicating motion between two pulleys requires a greater tension to prevent it from slipping when it runs at a high than at a low speed. Various suppositions have been made to account for this—such as that of the adhesion to the belt of a layer of air, which at a very high speed has not time to escape from between the belt and the pulley. But the real cause is simply the centrifugal force of the belt, which acts against its tension, and therefore slackens its grip of the pulleys. I have not hitherto seen or heard of any investigation of the laws of the action of centrifugal force on belts and other flexible connecting bands in machinery; and therefore, although it is unlikely that the subject has up to this time wholly escaped the notice of mathematicians, it appears to me that it may be useful to publish an account of the general nature of such an investigation and a statement of the practical rules to which it leads.*

For brevity's sake, the word "band" will be used throughout this paper to denote any flexible connecting piece by means of which motion is communicated between pulleys, whether a belt, a cord or a chain.

CENTRIFUGAL TENSION OF AN ENDLESS BAND.—The general principle of the tension produced in an endless band by centrifugal force is closely analagous to that which forms the foundation of the "hypothesis of molecular vortices," a hypothesis proposed in 1849† as a means of deducing the dynamical theory of heat from the general laws of dynamics, viz.: that a vortex or endless circulating stream produces an outward pressure against the inside of any vessel within which it may be contained, of an amount proportional to the weight of matter contained in an unit of length of that stream, and to the square of its velocity, and independent of the figure of the stream; for it can be proved, from the elementary laws of dynamics, that if an endless band of any figure whatsoever runs at a given speed, the centrifugal force produces an uniform tension at each cross-section of the band equal to the weight of a piece of the band, whose length is twice the height from which a heavy body must fall in order to acquire the velocity of the band.

In symbols, let w be the weight of an unit of length of the band; v the speed at which it runs, and g the velocity produced by gravity in a second (=32·2 ft. or 9·81 meters); then the *centrifugal tension* (as it may be called) has the following value:

$$\frac{w\,v^2}{g} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

There are different ways of demonstrating that proposition, the simplest being as follows: Consider any pair of cross sections of the band at which the motions of the particles are parallel and contrary. Call those cross sections A and B. The weight of band which passes any given cross section in a second is $w\,v$; the particles at A are moving with the velocity $+v$, and the particles at B with the equal and contrary velocity $-v$; hence, in each second, a mass of matter of the weight $w\,v$ undergoes a change of velocity amounting to $2\,v$; and, according to the second law of motion, the force in units of weight required to produce that change is $\frac{w\,v \times 2\,v}{g} = \frac{2\,w\,v^2}{g}$. One half of that force is supplied by the tension at A, and the other half by the tension at B; therefore the tension at each of those points is $\frac{w\,v^2}{g}$; and the same demonstration may be applied to every pair of points in the band at which the motions are contrary.

EFFECT ON THE BAND WHEN IN MOTION.—The effect on the band when in motion is, that at any given point the tension which produces pressure and friction on the pulleys, or *available tension*, as it may be called, is less than the total tension by an amount equal to the centrifugal tension; for this amount is employed in compelling the

---

* The general law of the centrifugal tension of a band is demonstrated in "Thomson & Tait's Elementary Dynamics" (Oxford, 1868); but it is not applied to questions of practical mechanics, which are foreign to the subject of that treatise.

† See "Transactions of the Royal Society of Edinburgh," Vol. XX, 1850–1851.

particles of the band to circulate in a closed or endless path. It is, of course, to the total tension that the strength of the band is to be adapted; therefore the transverse dimensions of a band for transmitting a given force must be greater for a high than for a low speed.

RULE FOR WEIGHT OF BAND.—One of the most convenient ways of expressing the size of a band is by stating its weight per unit of length—for example, in pounds per running foot, or in kilogrammes per meter. When the size is expressed thus, the corresponding way of expressing the intensity of any stress on the band is in lineal units of itself, such as feet or meters. Let b denote the greatest safe-working tension on a band of a given kind, in units of its own length; w, as before, the weight of an unit of length; so that $w\,l$ is the amount of the safe-working tension in units of weight. Let T be the amount of the available tension required at the driving side of the band for the transmission of power, being usually from two to two and a half times the force to be transmitted. Then the total tension is

$$T + \frac{w\,v^2}{g} = w\,l \quad . \quad . \quad . \quad (2)$$

whence it is obvious that the required weight per unit of length is given by the following formula—

$$w = \frac{T}{l - \frac{v^2}{g}} \quad . \quad . \quad . \quad . \quad . \quad (3)$$

For example, suppose that the band is a wire rope—that the greatest working tension is to be equivalent to the weight of 2,900 ft. of the rope, and that it is to run at 100 ft. per second, then we have

$$l = 2900 \text{ ft.};$$

$$\frac{v^2}{g} = 310 \text{ ft.};$$

and consequently the weight per running foot of the rope required is

$$w = \frac{T}{2900 - 310} = \frac{T}{2590};$$

or about one-eighth part heavier than the rope required for a speed so moderate as to make the centrifugal tension unimportant.

In fixing the value of the greatest working tension on a wire rope, a proper deduction must of course be made for the stress produced by the bending of the wires round the pulleys. That stress is given *in equivalent length of rope* by the expression $\frac{L\,d}{D}$ where D is the diameter of the smallest pulley round which the rope passes, d the diameter of the wire of which the rope is made, and L the modulus of elasticity of the wire, *in length of itself*—viz., about 8,000,000 ft. or 2,400,000 meters. That is to say, let l be the length of rope equivalent to the greatest safe-working tension on a straight rope; l, as before, the length equivalent to the actual greatest working tension, then

$$l = l_1 - \frac{L\,d}{D}{}^* . \quad . \quad . \quad . \quad (4)$$

In the case of leathern belts b may be estimated at about 660 ft. or 200 meters.

In the case of a leather belt running at the rate of 100 ft. per second, the weight per unit of length required in order to exert a given available tension is increased in the ratio of $\frac{660}{660-310} = \frac{660}{350}$, or to nearly double, as compared with that of a belt whose centrifugal force is unimportant.

The *sectional area of a leathern belt* may be calculated approximately in square inches by multiplying the weight per running foot by 2.3, or in square millimeters, by multiplying the weight in kilogrammes to the running meter by 1,000.

The ordinary thickness of a single belt being about 0.16 in., or four millimeters, the breadth may be deduced from the sectional area by dividing by that thickness.

The length (L) equivalent to the modulus of elasticity of a leathern belt, as calculated from Bevan's experiments, is about 23,000 ft., or 7,000 meters.

TENSION OF A BAND WHEN AT REST.—It is sometimes requisite to determine the tension which ought to be put upon the two sides of a band when at rest, in order that, when in motion, given tensions may be exerted at the driving and returning sides. The ordinary rule is to make that tension the arithmetical mean between the intended *available tensions* at the driving and returning sides of the band; and when the speed is such that the effect of centrifugal force is unimportant, that rule is sensibly correct.

It is sensibly correct also when the band connects two pulleys that stand a long way apart; for example, in Hirn's system of "Telodynamic Transmission," where the spans between the pulleys, that are connected by means of an endless wire rope, are sometimes 150 meters, or about 500 ft.

On the other hand, when the pulleys con-

* See Reuleaux, *Constructionslehre für Maschinenbau.*

nected by means of a fast-running band are comparatively near together, the tension which should be put upon each side of the band when at rest is nearly equal to the arithmetical mean between the *total tensions* of the two sides of the band when in motion; that is, the centrifugal tension has to be added to the tension given by the preceding rule.

In intermediate cases the tension, when at rest, has values intermediate between those given by the two preceding rules; and when the band connects two pulleys, whose axes are at or near the same level, it is expressed by the following formula, the result of a mathematical investigation, of which it is unnecessary to give the details here. Let l, as before, denote the length of band whose weight is equivalent to the total tension at the driving side when in motion; l' the corresponding length for the returning side; L the length equivalent to the modulus of elasticity; c the *half span*, or half distance between the pulleys; l_0 the length of band whose weight is equivalent to the tension required when at rest. Then, to a degree of approximation sufficient for practice, we have

$$l_0 = \frac{l+l'}{2} - \frac{v^2}{g}\frac{Lc^2}{2}\left\{\frac{1}{3l^3+Lc^2}+\frac{1}{3l'^3+Lc^2}\right\} \quad (5)$$

The two extreme cases, to which the two rules already given apply, are expressed as follows: When $\frac{Lc^2}{3l^3}$ is a very large number, we have l_0 nearly $= \frac{l+l'}{2} - \frac{v^2}{g}$, being the mean between the available tensions of the two sides; and when $\frac{Lc^2}{3l^3}$ is a very small fraction, we have

$$l_0 \text{ nearly } = \frac{l+l'}{2};$$

being the mean between the total tensions of the two sides of the band.

For example, let the band be a wire rope; let $v = 100$ ft. per second; so that $\frac{v^2}{g} = 300$ ft. Let the total and available tensions, when in motion, be as follows:

Driving side, $= 2,900;\ l - \frac{v^2}{g} = 2,590$

Returning side, $l' = 1,605;\ l' - \frac{v^2}{g} = 1,295$

Means,

$$\frac{l+l'}{2} = 2,252.5;\ \frac{l+l'}{2} - \frac{v^2}{g} = 1,942.5$$

Let $L = 8,000,000$ ft. of rope, and let the pulleys be 200 ft. apart, so that the half span $c = 100$ ft.; then the required tension at rest is found to be equivalent to the weight of the following length of rope:

$$2,252\tfrac{1}{2} - 215 = 2,037\tfrac{1}{2} \text{ ft.};$$

being intermediate between the mean of the total tensions and the mean of the available tensions, and somewhat nearer to the latter than to the former.

In order to show, in a general way, how the results expressed by the formulas and the rules are arrived at, it may be stated that the variations of the total tension, when the speed of the band alters, depend upon alterations in its length. When the pulleys are very near each other, the two sides of the band are sensibly straight, and its alterations of length are insensible, so that the total tensions at rest and in motion are sensibly equal, and the centrifugal tension takes effect almost wholly in diminishing the available tension. When, on the other hand, the pulleys are far apart, the two sides of the band hang in the form of curves; the band is free to alter its length to a certain extent; and part of the centrifugal tension takes effect in lengthening the band and increasing the total tension, instead of in diminishing the available tension; and hence the mean total tension is somewhat greater than the tension when at rest, and the available tension is not so much diminished as in a shorter band. If the span between the pulleys is wide enough, nearly the whole of the centrifugal tension takes effect in lengthening the band and increasing the total tension; and the mean available tension remains sensibly undiminished.

This accounts for a fact, well known to practical men, that in transmitting a given power between a given pair of pulleys, a long belt is less liable to slip than a short belt.

Coal from Sea-weed.—Some time ago the practice was introduced of converting marine algæ by calcination into an excellent coal superior to ordinary wood charcoal for filtering water, disinfecting sinks, polishing glass and correcting the acidity and decolorizing wines,—also for precipitating and decolorizing vegetable alkaloids.—Until recently no value was attributed to the marine algæ—to-day it is an important article of commerce in several islands.—*Annales du Génie Civil.*

EXPLOSIVE COMPOUNDS FOR PROJECTILES.

From "The Mechanics' Magazine."

Gunpowder, which has been in use for so many years, may now be considered as perfect as it can be made, as regards projectile force and uniformity of combustion. Recent attempts have been made to employ it in a more condensed form, by compressing the charges, but these have failed to a great extent. Of late years, several new explosive compounds have been manufactured as substitutes for gunpowder, and they have, for the most part, been described in our columns. It is claimed for them, generally, that they possess greater cleanliness, almost total absence of smoke, less sensible recoil for a given velocity of projectile, and reduction of danger in manufacture, as being less violently explosive in an unconfined state.—These may be considered as the general claims to superiority of the new explosives. Being principally composed of vegetable fibers nitrogenized, they might aptly be termed explosive fibers. Those now in use are known as gun-cotton, wood-powder, and gun-felt. As a few years' experience only in the production of these compounds can be placed against as many centuries in the production of gunpowder, it is reasonable to expect further progress and improvement in these new substances. When gun-cotton was first discovered, its obvious advantages induced several governments to adopt it in the place of gunpowder. The nature of this substance, however, not being thoroughly understood, many serious accidents resulted from its use. The too rapid combustion injured arms in which it was employed, and it was further found to lack uniformity in firing; in fact, for the most part, gun-cotton was abandoned in disgust. Recently, however, many ingenious methods have been adopted to retard this great rapidity of combustion, and although gun-cotton can be and is used in shot-guns with comparative safety, still it has not yet been produced with sufficient uniformity or slowness of combustion to shoot accurately in rifles. Until this be done, it cannot be considered as a perfect substitute for ordinary gunpowder. Gun-cotton, however, can now be produced in such a condition that it may be stored with safety and without fear of deterioration; and thus prepared, it is largely used for mining and engineering purposes.

Schultze's wood-powder is composed of minute cubes of hard wood, treated in a manner analogous to gun-cotton, and subsequently impregnated with other substances; it is used in a pure state, and requires compressing with considerable force, in order to obtain the best results. It can be fired in rifles, and this is a proof of a certain amount of uniformity, though it occupies a greater volume than gunpowder to give an equal initial velocity to the bullet. Reeves' gun-felt—another comparatively recent invention—is composed of vegetable fibers, which are also treated analogously to gun-cotton, and subsequently impregnated with other materials. This compound is also used in a pure state, and can be fired in rifles. This material was invented and is now being manufactured by Messrs. Reeves & Co., of Glastonbury. It has been found to answer exceedingly well, both in sporting guns and in rifles, but, pending some practical trials which are to be made with this material in a short time, we defer a further reference either to its composition or its special performances. These two last mentioned compounds are made of several different strengths, and the weight of charges used relatively to gunpowder is, of wood-powder, about one-half, and gun felt one-third, *i. e.*, one is three times and the other double as strong as ordinary powder. These new explosives ignite at a much lower temperature than powder, but being composed of less solid matter, the combustion generates less heat, and as many rounds can be fired in a gun or rifle with as much safety as with gunpowder. The fouling is also considerably lessened; the ignition, although quick, does not impart the same sensible recoil. The more solid forms of fiber, such as wood-powder, give more recoil than gun-felt, from which it may be inferred that the elasticity of a compound to a certain extent checks in itself the sudden shock of ignition.

The reduction of recoil in military weapons is of some importance, as it limits the weight and velocity of the bullet. Action and reaction on the bullet and breech of gun may be the same, but when the gases are generated in a gradual manner, the sensible recoil must necessarily be reduced. Even with gunpowder this can be proved by experiment, as quick burning powder will give much greater recoil, with the same initial velocity imparted to the bullet, than a slow burning one. No doubt, the great portion of the motive power exerted by explosives is instantaneous in its action, and ought not to be generated before it is required to act on the projectile. A gas, doubtless, is elastic according to its density, and, if permanent in this respect (such as steam or compressed air), could not be generated too quickly to give velocity to a projectile. But with all explosives, the reverse has been shown to be desirable, *i. e.*, provided a given charge will consume in a barrel before a bullet quits the muzzle of the arm. The slower the combustion the greater the velocity communicated to the bullet, the friction in the barrel being greatly reduead. Last year, a public trial took place with a view of testing the new explosive substances. Some very fair shooting was made with wood-powder and gun-felt at 100 yards' range in rifles, the latter equalling gunpowder in accuracy, and the former within 30 per cent of it. If there is to be any competition this year, it is to be hoped that it will be at long ranges, that being the true test with rifles, reference being made to the angle of elevation and absolute deviation. As already intimated, some further comparative experiments are to be made with Schultze's wood-powder and Reeves' gun-felt, to which we look forward with interest, and the results of which we shall place before our readers.

UNDULATING AND LEVEL RAILWAYS.

RELATIVE EXPENSES OF TRACTION.

From "Engineering."

A problem often and long discussed by railway engineers abroad is that known as the "equation of gradients;" or, in other words, what additional length of line, taken as level, is represented by given gradients of a given length and inclination? Two lines are, each, 100 miles in length. One is, we will suppose, a dead level; the other has rising and falling gradients, ascending and descending at rates varying from 1 in 1,000 to 1 in 60. How much longer, not in actual distance, but in respect of working expenses, is the latter than the former? We are in the habit of lumping all railway expenses at so much "per train mile," the train being either passenger or goods, and containing, in the former case, anywhere from 15 to 1,000 passengers, and in the latter, anywhere from 20 to 300 tons of goods. But we are to suppose the same trains over both the lines just assumed. Let the undulating line start with a mile of level, then five miles up of 1 in 1,000, then four miles up 1 in 100, then two miles more up 1 in 80, to a summit 369.6 ft. above the starting point. Let it then run eight miles on a level; then descend at the rate of 1 in 200 for five miles, falling 132 ft.; then five miles of level; then ten miles up 1 in 264, *i. e.*, rising 200 ft.; then five miles up 1 in 132, rising 200 ft. more to a point 637.6 ft. above the base. Let it then have five miles more of 1 in 60, or an additional rise of 440 ft., giving a summit, midway between the termini, 1,077.6 ft. above the starting point. Let the line then descend at the rate of 1 in 200 for five miles, falling 132 ft., then rise for ten miles at the rate of 1 in 400, thus rising again to the summit of 1,077.6 ft. Let it then descend for twenty miles at the rate of 1 in 132, thus falling 800 ft. Let the line fall thence for ten miles at the rate of 1 in 264, the fall being 200 ft., and let the remaining fall of 77.6 ft. take place in the last five miles.

Those who take any interest in the subject will sketch out the profile for themselves; those who do not will turn to another column and read something else.

It will be seen that the line has a maximum gradient of 1 in 60 for five miles in one direction, and a maximum of 1 in 132 for twenty continuous miles in the other. The sum of the ascents from either terminus would be 1,341.6 ft., while the total rise and fall would be, of course, twice as much, both termini being at the same level. Supposing the same trains to be run over the level and the undulating line, how much longer is the latter than the former—not in actual measurement over its various undulations, for that is easily calculable, and in any case very little—but what length of level line could be worked at the same expense? It will require but little consideration to perceive that the question involves many points as to speed, number of stops, position of stations, the preponderance, if any, either way, of the traffic, &c.

Suppose, however, trains of a total weight, including engine, of 100 tons, are to be run through, each way, stopping only midway. The speed on the level line to be 40 miles an hour, requiring $2\frac{1}{2}$ hours running time. The resistance, by Clark's formula, would be 1,735 lbs., corresponding, at 3,520 ft. per minute, to 185 horse power maintained for $2\frac{1}{2}$ hours.

On the undulating line the train, apart from all other resistances, would be lifted 1,341.6 ft. in ascending the various gradients from either end, and if this ascent occupied an hour and a half, the average work expended upon gravity during that time would be 101 horse power. For

$$\frac{224{,}000 \text{ lbs.} \times 1341.6 \text{ ft.}}{2{,}970{,}000 \text{ ft. lb.}} = 101 \text{ H. P.}$$

The 224,000 lbs. being the weight of the train, and the divisor, 2,970,000, the number of foot pounds in a horse-power, exerted for an hour and a half; corresponding to 33,000 ft. lb. in one minute. If the mean speed of ascent from one end of the line to the half-way summit be 33⅓ miles an hour, as above assumed in the estimate of an hour and a half, the resistances other than gravity will be

$$8 + \frac{33.3^2}{171} = 14.5 \text{ lb. per ton, or } 1{,}450 \text{ lbs.}$$

for the entire train, at 2,933⅓ ft. per minute, corresponding to 129 horse-power, or, including gravity, to 230 horse-power for an hour and a half, as against 185 horse-power for an hour and a quarter in doing the same distance on a level.

But we now come to the descent, and here it is difficult if not impossible to estimate—not the resistances to motion—but the exact practical effect of descending gradients upon the cost of working. Less fuel and water are of course used, but the actual forces at work upon a train are the same, at a given speed, in descending as in ascending an incline; the difference being merely that gravity takes the place of steam power. If, indeed, as is almost certain to be the case, the speed be greater in going down than up a given incline, on a double line—and supposing the traffic to be equal in both directions—the rails on the down side will, after a time, be invariably found to be more worn than those on the up line, although they are not subjected to the same grinding action from the driving wheels of the engine. Almost the only saving on down gradients is in fuel and water. If no steam be used the cylinders must be kept well lubricated, the attendance or cost of engineman and fireman, is the same, the wear and tear, except upon the fire-box and tubes of the engine, is certainly not less, and if it be necessary to put on the brakes, it is apt to be more. In these respects alone, long down gradients, of considerable inclination, may be taken as involving a working cost equal to that of levels, although, unfortunately, no data are at hand to show that they are neither better nor worse than levels. There are other and considerable items of expense which are wholly independent of gradients.

Regarded, then, as levels, the descending gradients either way from the midway station would require the exertion of 185 horse-power for an hour and a quarter, the ascent requiring 230 horse-power for an hour and a half, thus giving a mean expenditure of 209½ horse-power for 2¾ hours on the undulating line, as against 185 horse-power for 2½ hours on the level. Allowing for both the greater horse-power and longer time on the undulating line, it would be 24½ per cent, or, say one-fourth more expensive in working than the level. In other words, the 100 miles of undulating line are practically 110 miles in point of time and 124½ miles in point of cost of working, as compared with the 100 miles of level line. This estimate assumes that the cost of fuel, repairs, wages, &c., are in the exact ration of the horse-power exerted, after adopting the explanation given in respect of descending gradients.

The assumptions which enter into these estimates are by no means conclusive, and they would be greatly affected by the substitution of heavy slow traffic in place of fast passenger traffic. Thus, in the American States, the rule for the "equation of grades" known as Latrobe and Knight's, is to divide the sum of the ascents and descents in feet, by 52.8, and to add the quotient to the length of the line in miles, as the equivalent length of level line. By this rule, the total rise and fall of 2,683.2 ft., in our suppositious line would represent $\frac{2{,}683.2}{52.8} = 50.8$ of additional length, and with a moderately slow goods traffic, this addition would hold good in practice.

There are various aspects of the question of gradients, and different engineers would doubtless take different views of it. But the extra expenditure of power must be as the total rise of the line, and is, in a measure, independent of short, steep and exceptional gradients. With a train of a total weight of 100 tons, any engine with 15 tons of adhesive weight should have no difficulty in dealing with it on a gradient, however long, of 1 in 60; and if the gradient were not above five miles long, occupying ten minutes in the ascent, at the rate of thirty miles an hour, the boiler power required would not be found excessive, supposing the water well up and the pressure high, on entering upon the gradient.

In taking out the cost of working as 24½ per cent more upon the undulating than upon the level line, this represents much more than the extra fuel used, and more than the extra wages incurred. It represents, perhaps, more properly, the increased cost of lubrication and repairs, including repairs of permanent way. Of the latter, however, a large share is due to climatic and local causes, and is independent both of the resistance of trains and the amount of traffic. A large proportion of the general traffic expenses is wholly independent of the resistance of trains, so that, as affecting dividends, the gradients assumed would not probably diminish the net earnings derivable from a level line by more than 6 per cent, equal perhaps to 1 per cent on the capital of the line.

Compound Steel and Iron Rails.—Mr. Ashcroft has laid a quantity of compound rails on the Charing Cross line. The top member is a Bessemer steel ┬. The two bottom members are wrought iron angle pieces _| |_, bolted together. The rails are said to answer well. Much attention is being directed in this country to the production of a good compound steel and iron rail. The old compound iron rail, with a split head, failed chiefly by the mashing down of the iron into the continuous crack in the head, and the forcing apart of the two members. The compound rail, with a solid head and a split foot, did tolerably good service; the grand defect was the riveting of the two members together so tightly that they could not slip upon each other when expanded by heat. Making the top member of steel and bolting the two together, would undoubtedly make a durable rail. The general plan of Mr. Ashcroft would, however, appear to be better. A modification of this plan is being developed at one of our rail mills.

Steel-headed rails should be cheaper than all steel rails, and they should give nearly all the advantages of steel as far as wearing is concerned. Of course they cannot be so stiff nor so strong as all steel. The use of three, or even of two members, overlapping each other, almost insures against disasters from broken rails. Steel heads welded to iron piles do not possess this advantage, although there is much to be said in their favor. The different plans will be considered at another time. The attention of experts is just now chiefly directed to the production of compound rails with steel heads. Besides immunity against accident from breaking, another great advantage expected from this construction is the permanence of the iron parts. It is believed that the steel heads only will require renewal; and this only after they have worn a dozen times as long as iron heads; and that the iron angle pieces forming the flanges and web of the rail will be practically indestructible. There must, we think, be some wear between the parts thus subjected to abrasion. Nevertheless the economy to be reasonably expected from compound steel and iron rails is very great, and it is probable that railway companies will hasten to avail themselves of the proposed advantages as soon as they are offered.

Coiled Tube Boilers.—It was once thought that the perfection of boiler construction had been arrived at in boilers made on the coiled tubular system. This principle, however, soon showed a radical defect which led to its abandonment. Boilers so constructed failed on account of the tubing becoming red hot when the engine was standing, and the force pump was consequently not acting. This defect, however, has been practically overcome by Mr. Thomas Mills, of England, in an invention described by the London "Mechanics' Magazine." Mr. Mills constructs the fire-box of a boiler, of the upright form, of a coil of tubing enclosed in a case, the fire-box being contained within the coil. The bottom of the coil is connected by a tube brought down outside the casing from the upper part of the boiler, at the lower end of which tube is fixed a self-acting valve placed in a horizontal position, which allows the water to pass on into the coil. The expansion of the water caused by its coming in contact with the heated tubing closes the valve after it has passed through it, and thereby prevents a backward flow of water through the outside tube, and forces the water and steam on through the coil into the upper part of the boiler again. After this, the valve again opens, in consequence of the downward force of the water in the outside tube, thereby creating a perfect circulation through the coil, the discharge end of the coil being brought up inside through the bottom of the upper part of the boiler above the water level. The coil can also be supplied with water by means of a pump worked by the engine (the stroke of the pump being altered according to the quantity of water required to supply the boiler), and cutting off the other supply of water by means of a cock fixed in the outside tube connecting the upper part of the boiler with the lower end of the coil, thereby feeding the boiler with water through the coil without in the least degree reducing the volume of steam. This method of feeding the coil by the outside tube and valve brings the water direct into the hottest part of the coil, and keeps up a perfect and continuous circulation without the aid of the force pump. This pump is used to feed the boiler through the coil, which is a great advantage in itself, as the cold water does not come into direct contact with steam contained in the upper part of the boiler, which causes loss of steam by condensation. Mr. Mills has made practical trials of this improved system of construction, and finds it to realize the following advantages—economy in every respect, rapid generation of steam, great strength, and almost entire freedom from explosion, together with lightness and simplicity. He states that it raises steam from cold water in less time than any other boiler at present in use. The circulation through the coil being exceedingly rapid, no deposit is found to remain in it. The self-acting valve or clack is so simple in construction that it cannot fail.—*American Railway Times.*

WORKING HEAVY GRADIENTS.

Compiled from a paper before the Institution of Civil Engineers, (Feb. 2, 1869,) by Mr. James R. Mosse, M. I. C. E., on the "Mauritius Railway—Midland Line."

The Gradients.—The character of the gradients on the Midland line will be understood from the following summary: From Port Louis to the summit there was a rise of 1,817 ft., the distance being about 16 miles, or equal to an average gradient of 1 in 46.68; and from the summit to Mahebourg, a distance of about 19 miles, there was a descent at the rate of 1 in 55.61. For about 12½ miles before reaching the summit the inclination was on an average of 1 in 41.17, and thence for about 13½ miles the line fell on an average 1 in 45.06. The steepest gradient was 1 in 27, of which there was a total length of 13,526 ft., the greatest continuous length of this gradient being 6,163 ft., and the next longest 5,016 ft. The next in severity was 1 in 30, the total length being 9,526 ft., the greatest length of this gradient being 3,000 ft., and several lengths of about 2,000 ft. each. The ascending gradients varied from 1 in 27 to 1 in 60, while the descending gradients towards Mahebourg varied from 1 in 30 to 1 in 60. The curves varied from 950 ft. radius to 6,000 ft. radius, and the lengths of these curves ranged from 200 ft. to 3,200 ft. The ordinary radii were generally from 2,000 ft. to 3,000 ft. The sharpest radius which occurred on the steepest gradients of 1 in 27 and 1 in 30 was 1,600 ft., the greatest continuous length of this curve being 900 ft. on the former gradient, and 1,930 ft. on the latter. The next radius in severity was 2,000 ft. on the maximum gradient of 1 in 27, the greatest continuous length of this curve being 1,000 ft. Reverse curves of this radius 1,920 ft. in length were also found on the maximum inclination of 1 in 27. On descending from the summit to Mahebourg the line from the 17th mile to the 19th mile might be said to be composed wholly of reverse curves, and at the 29th mile the radius was only 1,400 ft., the length of this curve being 1,980 ft., chiefly on a gradient of 1 in 30. Of curves under 2,000 ft. radius there was an aggregate length of 21,165 ft; of those ranging from 2,000 ft. to 4,000 ft. radius there was a length of 49,710 ft.; and of curves from 4,000 ft. to 6,000 ft. (the greatest radius), there was an aggregate length of 25,560 ft., the total length of curves being 96,435 ft., and of the straight portions of the line 89,467 ft.

The Locomotives.—The locomotives furnished under the original contract for working these inclines were seven in number and of the following description: they were tank engines, having cylinders 16 inches in diameter, with a length of stroke of 22 in.; the wheels, six in number, were 3 ft. 6 in. in diameter, and were all coupled, the length of the wheel-base being 15 ft. When supplied with water and fuel these engines weighed nearly 37 tons, and they were worked with a pressure of steam of 120 lbs. per square inch. Subsequently six larger saddle-tank locomotives were designed by Mr. Hawkshaw, having the following dimensions: cylinders 18 in. in diameter, with a length of stroke of 24 in.; the wheels, eight in number, were 4 ft. in diameter, and were all coupled, the length of the wheel-base being 15 ft. 6 in. When supplied with water and fuel, these engines weighed nearly 48 tons, and they were worked with a pressure of steam of 120 lbs. per square inch. The center pairs of wheels (one of which was the driving pair) were fixed stiff on the frame; but in order to pass easily round the curves, both the leading and the trailing wheels had three-quarter inch play on each journal, and the joints of the coupling rods, connecting these wheels with the driving pair, were fitted with a ball and socket, so as to allow the requisite motion. All the engines were manufactured by Messrs. Sharp, Stewart & Co., and worked very satisfactorily. These engines would, with passenger trains, take five carriages and one brake-van, equal to a load of 42 tons, though on some occasions they had hauled eight loaded vehicles, weighing in all about 56 tons; while with goods trains the usual load with the lighter locomotives was 70 tons, and with the heavier locomotives from 100 tons to 120 tons. It should, however, be stated that by reducing the lead of the slide valves to one-eighth of an inch, the power of these engines had recently been increased 10 per cent.

Speed and Duty.—The average speed of the passenger trains, including stoppages, was 12 miles per hour between Port Louis and the summit, and 15 miles per hour from Mahebourg to the summit; while that of the goods trains was about 9 miles an hour, including frequent stoppages. The particulars of a trip made on the 12th December, 1867, when the fuel and water were noted more accurately than usual, were given in detail. From these it appeared that the train consisted of ten loaded wagons weighing together 83 tons, or with the engine a gross load of 131 tons; the average speed from Port Louis to the summit was 11 miles per hour, and taking the average pressure of steam in the cylinder as 60 lbs per square inch, the power exerted would be $\frac{131\times60\times11\times88}{33,000}=230$ H. P. or, not including the weight of the engine, 146 H. P., and this, divided by the weight of the locomotive, was equal to 3.04 H. P. per ton of motor. The coal used on the above trip was obtained from Sydney, N. S. W., and the consumption amounted to 4.75 lbs. per H. P. per hour, 8 lbs. of water being evaporated by 1 lb. of coal, but ordinarily only $7\frac{1}{2}$ lbs. of water were evaporated by 1 lb. of this coal.

Carriages and Brakes.—With the exception of the first-class carriages all the others on this railway had a brake on every wheel, worked from the inside. The ordinary passenger trains were composed of one first, one second, and two third-class carriages, with one brake-van, and to these trains Mr. Clark's continuous brake was attached. This apparatus was worked by a chain, which tightened the brakes on every one of the wheels simultaneously. The brakes were taken off by heavy counter-balance weights, resting longitudinally over the chain in the center of the carriage, between the front and end wheels. This apparatus was sufficiently powerful to lock every wheel, and had worked satisfactorily; for during two years there had not been a single fracture of the chain, nor of any of the working parts. It, however, required careful management, and must be applied gradually, before the train had acquired serious momentum. The brake-van of every passenger train was now provided with sand boxes leading to the rails, as formerly the dew on the rails wetted the wheels of the brake-van, and prevented the friction rollers of the apparatus from revolving; whereas, as soon as sand was applied, the wheels became dry, and the friction rollers acted efficiently. Every train of four or five carriages had two guards, one to work the continuous brake, the other to use the separate brake, if necessary, attached to that carriage which was not connected with the continuous brake. The heaviest passenger train which had descended from the summit to Port Louis consisted of fourteen carriages and two brake-vans, conveying five hundred and thirteen troops. That was on the 14th November, 1868, and it was kept perfectly under control by the continuous brake on four carriages, and by five additional brakesmen, the speed being steadily maintained at 20 miles per hour. There were but four instances of passenger trains getting for a time beyond control: first, one morning when the rails were wet, a train descended from the summit for a distance of $3\frac{3}{4}$ miles in five minutes, or at a speed of 45 miles per hour. This was the highest speed on record, and it occurred before the sand boxes were put on the brake-vans. Secondly, in a similar way, another train attained a speed of 32 miles per hour. Thirdly, a train overran a station for a considerable distance, chiefly from the want of sufficient care on the part of the engine driver and guards. Lastly, a train once attained an excessive speed in descending from the summit, through the dropping off of the nut of the eyebolt passing through the axle on which the continuous chain of the brake apparatus was wound. The speed in descending the inclines was limited theoretically to 18 miles per hour, practically it rarely exceeded 25 miles, and the carriage brakes were generally sufficient to control the train, without the necessity of applying the engine-brake. The goods trains in descending the inclines as a rule consisted of eight loaded wagons with the lighter locomotives, and of ten or twelve wagons with the heavier engines; and in these cases also the brakes on the wagons, two being screw brakes, and the remaining wagons being furnished with the ordinary lever brakes, afforded power sufficient to control the trains. It had long been in contemplation to make safety sidings at the foot of the steepest inclines, but the ground was by no means favorable for the purpose, and, moreover, it was feared that such sidings might become a source of danger.

Cost of Working.—The rules in force for the regulation of the traffic on the main line and at the stations were then given in detail, as well as the traffic returns for the years 1866 and 1867, the rates for passengers and goods, and the statement of the receipts and expenditure for the year 1866, from which latter it appeared that the working expenses were then $62\frac{1}{2}$ per cent of the receipts; but this result was said to be due to several exceptional causes. Considering the high price paid for skilled labor and for fuel, the agricultural character of the district through which the line passed, the severity of the gradients, the want of anything that could be called a town save at Port Louis, the lack of minerals or manufactures to transport, the peculiar nature of the sugar traffic—requiring a large amount of rolling stock for three months in the year, whereas for the remaining nine months less than half the quantity sufficed—the author thought it was not surprising that the working expenses of the Midland line should in 1866 have been $62\frac{1}{2}$ per cent of the receipts, or 5s. 5d. per train mile. Now that the heavier locomotives enabled a larger amount of sugar to be carried, and when the goods traffic was further developed, it was believed a considerable decrease in the percentage of working expenses to receipts would ensue, accompanied also, it was hoped, by a reduction in the cost per train mile.

Conclusions.—In conclusion it was remarked, that although it might sometimes be impossible to construct a railway with easier gradients than those on the Midland line, yet the difficulty of working these inclines in wet weather had been so great, the load hauled so small, and the speed so low, that the author thought the severity of any gradient for a long rise should never exceed 1 in 40; and that it would always be preferable (under the ordinary system of tractive power), to incur, within reasonable limits, any additional expense that might be requisite to bring the inclination within this ratio. It was also suggested that in laying out such inclines, whatever might be the ruling gradient (provided it was not entirely exceptional, and where additional power could be applied), that gradient should be followed throughout the line, as far as the features of the country would permit. It was likewise recommended, that pieces of level should be introduced between the different inclinations, as they were of the greatest value, in controlling the trains in descending. The Midland line had now been opened for more than three years, and fortunately no accident had yet occurred to any train in descending the inclines.

SUBMARINE ENGINEERING.

SINKING BRICK AND IRON PIERS—SAND PUMP—NEW EXCAVATOR.

From a paper by Mr. Imrie Bell, M. I. C. E., "On sinking wells for the foundations of Piers and of the Bridge over the River Juma, Delhi Railway," and a paper by Mr. John Milroy, Assoc. I. C. E., entitled "Description of Apparatus for Excavating the interior of and for sinking Iron Cylinders," before the Institution of Civil Engineers, March 2d, 1869.

Sinking Brick Piers.—The mode of forming the foundations of the bridge over the river Juma, was thus described by Mr. Bell: It appeared that the bed of the river at this point consisted of coarse and fine gravel and sand, interspersed with layers of blue clay 3 ft. and 4 ft. thick, and covered with silt; but during the rainy season large boulders, weighing 14 lb. each and upwards, were brought down and deposited by the scour of the river 30 ft. below the level of the bed. The bridge comprised twenty-four openings, each 99 ft. in the clear, and the superstructure was composed of two lines of lattice girders, resting on brick columns or wells, each 12 ft. 6 in. external diameter, and 5 ft. 10 in. internal diameter, so that the wall of the well was 3 ft. 4 in. thick. In some instances the sites of the piers were got clear of water by diverting the river at different points during the dry season, while in other cases islands were formed, by driving a half circle of piles on the up-stream side, then lowering sand-bags on the down stream side, to the height of 4 ft. or 5 ft., and afterwards filling up with sand to 5 ft. above low water. The curb on which the steening of the well rested was formed of wrought-iron plates and angle irons riveted together; and in cross section the curb was like an inverted right-angle triangle, of which the height was 4 ft. and the base 3 ft. 4 in. When each curb was complete it was moved into position, and the compartments were then filled in with concrete. The curb was next sunk by men working with the "phaora" (spade) and basket, till the upper edge was within 3 in. of the level of the water, when a ring of brick work was carried up for a height of 6 ft. The excavation of the interior was again proceeded with by means of the "jham" and divers in the old native style; afterwards a further height of 10 ft. of brick work was added, but the material was now removed by a sand-pump (to be hereafter described) worked by a steam hoist of 4-horse power, as was the case after two additional lengths, each of 15 ft., were built, when the well was carried down to its full depth. In operations of this nature great care was necessary, especially at first, to insure the well or cylinder descending vertically. For this purpose the curb should invariably be sunk alone without any building. The first height of brick work should not exceed 5 ft. or 6 ft., the next 10 ft., and it was never advisable to build more than 15 ft. at a time. Before commencing any additional height the top course of the brick work already built ought to be removed, to insure a thoroughly clean surface for the mortar.

Lime and Mortar.—The lime used at the works was made from marl or, more properly, calcareous clay, which, while soft, was roughly moulded into bricks. These were stacked to dry for three or four days, and were afterwards burned with wood in kilns for fifty or sixty hours. The flues were then closed with bricks and mud, and so allowed to remain for two or three days. On the kiln being opened the lime bricks were unloaded almost in a whole state, were ground under stones, screened, and carried to the works pure and free from ash or dirt. The mortar was made from one part of ground lime and one part of clear, sharp sand. This mortar was used in all the well foundations of the bridge up to the level of low water; and as a proof of its quality it was stated that it was easier to break the work as a mass than to separate it at the joints or beds. Above the level of low water the mortar was composed of white hill lime, and sorkhee, or crushed brickbats, in equal proportions, as it was found that the lime from the calcareous clay lost the greater part of its cohesion when used in work exposed to the vicissitudes of the atmosphere—whether this arose from the frequent changes from dryness to humidity, or from heat to cold, was not ascertained.

Time Occupied.—The well sinking for the foundations of the piers and the abutments of this bridge was completed in little more than two years, which, without deducting any time for building up the brick work, or for that unavoidably lost by the rise in the river during rains, gave an average rate of 159 ft. per month. The time occupied in the building of the steining of the wells, erecting, taking down, and reërecting scaffolding and staging for sand-pump, weighting the wells, &c., was equal to that employed in sinking. This would give the rate of sinking as a little over 300 ft. per month. If cast-iron cylinders had been used, the work could have been performed much more quickly, as the portions of the cylinders could have been put together more rapidly, and owing to the slight bearing surface exposed by the thickness of the iron, compared to the breadth of the brick work in the walls of the well. The total weight of the foundations and of the iron girder superstructure on each well was 420 tons, and the area of the bottom of each well was 117 ft., so that the weight was less than 4 tons per square foot.

The Sand Pump.—The novelty in the sinking of the wells of this bridge was in the use of the sand pump. This was described to consist of a wrought-iron cylinder having a pump riveted to it at the top, in which was a piston fitting loosely, and pierced with small holes to allow of the escape of water. The piston rod terminated in an eye at the upper end, to which a chain could be attached. The bottom of the cylinder was movable, and in the center there was an upright suction pipe, projecting outwards for a distance equal to its own diameter, and inwards nearly to the top of the cylinder. When the pump was lowered to the bottom of the well, the chain attached to the piston rod was worked up and down like a ringing engine. In this way water was first drawn through the upright pipe, followed by sand or other material, which fell over the pipe into the cylinder. This operation was continued until the cylinder was quite full, which was known by the piston working stiffly, when the machine was raised to the surface; the bottom of the cylinder was then detached, with the column of sand resting on it, and another cylinder bottom which had been cleared of its sand was substituted. The number of men employed at each well was fourteen, nine working the chain, two clearing away the stuff brought up by the pump, one in charge of a steam hoist, one breaking firewood, and an overseer. The average rate of sinking, including contingencies, was about 6 ft. in eight hours. This rate was extraordinary when compared with the old system of the "jham" and diver, and would, it was believed, materially reduce the expense of bridge work in India.

Milroy's Excavating Apparatus.—Mr. Milroy believed that for the purpose of sinking cylinders, the great desideratum hitherto had been some method of excavating the earth from the interior without at the same time having to take out the water, and to keep it out during the operations. This object seemed to the author to have been attained by a machine of his invention, which was used in the construction of the bridge over the river Clyde, for the Glasgow (City) Union Railway, to which Mr. Fowler and Mr. Blair were the engineers.

The excavating apparatus, commonly called the "excavator," was thus described: It consisted of a horizontal frame of iron, with an outside rim 9 in. in height, to which radiated, like the spokes of a wheel, T-irons from a small cast-iron ring in the center. To the bottom of the outside rim were hinged eight heavy iron spades, which, when drawn in, fitted closely, with their points pressing against the inner ring. The hinges of the spades were so constructed as to prevent them from turning back beyond the perpendicular. The whole apparatus was very strongly made, and it formed, when closed, a nearly water-tight tray. When the machine was descending the spades were allowed to hang vertically, and they were forced into the ground by the aid of two chains fastened to the top of upright arms on opposite sides of the excavator, then passed down the cylinder, under a pulley, up between two leaders, and over another pulley, the end of each chain being wound round the large axle of the capstan, or drum, on the landing stage. These chains were calculated, when tightened, to keep the machine down, whilst the spades were being drawn in through the crowd, and up to the frame. This was effected by a second set of chains, all of equal length, and each fastened at one end to the inside of a spade, and at the other end to the end of a main chain, by which the machine was raised to the surface, with the earth it contained, by means of a steam hoist. In order to enable an opinion to be formed of the capabilities of the excavator, it was mentioned that the progress of the excavation, and the corresponding subsidence of the cylinder, reached from about 12 ft. to 20 ft. per day of ten hours, inclusive of the time employed in adding fresh lengths of cylinder, putting on weights, &c. When there had been little interruption for any of these purposes, it had amounted to 25 ft. in the ten hours, and then the average quantity of sand brought up at each lift was 21 cubic feet, and the total quantity during the day was found, by measurement, to be 70 cubic yards. Twelve men in all were employed, viz: one engineer, one stoker, six men working the drums, three attending to the loading and discharging of the excavator, and one man wheeling away the materials.

In conclusion, the following advantages were claimed for this apparatus: First, that it was perfectly independent of water, which was allowed to remain in the pit or cylinder until the excavation was completed; secondly, that it could be used, and was equally effective, at any depth, without sensible difference in the cost of working; thirdly, that its rate, both of sinking and of excavating, was higher than had yet been attained by any other method; and lastly, that it was not liable to get out of order, whilst its action was always in the same perpendicular line, and the expense attending its working was comparatively trifling, as skilled workmen were not required.

Chimney Sweeping "Engineering" in Amsterdam.—There has recently been formed in Amsterdam, with the Royal approbation, a nondescript association with the title, "*Amsterdam Soot Company.*" The director has the title, "Royal Chimney Engineer;" the managing agent is a distinguished advocate of that city, and the commissioners designated by the government are, an inspector of public works, a great diamond merchant, already president of one industrial association, and an architectural engineer, who is also a manufacturer. The company has for its business the sweeping of chimneys and trade in soot.—*Annales du Génie Civil.*

TEN-WHEELED FREIGHT ENGINE—PENNSYLVANIA RAILWAY.—One of these engines, as designed by Mr. J. B. Collins, Mechanical Engineer to the Company, is fully illustrated in "Engineering," March 5th. The intention in the design was to embody all improvements developed by experience, and to omit all superfluities of construction. In the finish of the engines there is no attempt at ornamentation; there are no brass bands about the boiler, and there are no brass accessories, except the bell and whistle. The painting is plain, and no scroll-work or pictures are introduced. The object sought, in fact, has been to make a plain serviceable engine, without any unnecessary ornamentation. The principal dimensions are as follows:

	ft.	in.
Cylinders.		
Diameter	1	6
Stroke	1	10
Distance apart from center to center	6	9
Length of ports	1	4
Width of steam ports	0	1¼
Width of exhaust ports	0	2½
Width of bars	0	1
Distance from center of cylinder to valve face	1	3⅝
Lap of valves	0	0¾
Travel of valves in full gear	0	5
Wheels.		
Diameter of coupled wheels	4	7
Diameter of bogie wheels	2	4
Distance between center of bogie wheels	5	8
Distance from center of bogie to center of 1st pair of coupled wheels	8	5
Distance between centers of 1st and 2d pairs of coupled wheels	5	0
Distance between centers of 2d and 3d pairs of coupled wheels	7	5
Total wheel base	23	8
Boiler.		
Diameter of barrel outside largest plate	4	2
Length of barrel	11	11
Length of fire box casing	5	9¼

The four-wheeled bogie under the front end of the engine is of the ordinary pattern, with a swing beam, and the front pair of coupled wheels has tyres without flanges. The bogie is fitted with the usual chilled disc wheels, and the coupled wheels are of cast-iron with hollow spokes and rim. The connecting rods take hold of the crank pins on the center pair of coupled wheels, and the eccentric rods are cranked so as to pass respectively above and below the front pair of coupled wheels to the links. The valve faces are situated above the cylinders, and the valves are worked through the intervention of rocking shafts, as is usual in American engines.

LIGHT RAILWAY ROLLING STOCK.

From "The Engineer."

That railways do not pay a fair profit on the sums invested in their construction is a truth fully recognized by the modern capitalist. This truth, so important in its bearing on the development of the resources of the country, has been carefully investigated by engineers and financialists alike, and, as a result of this investigation, two general propositions have been laid down. The first is, that very large sums have been in some cases necessarily, in other cases unnecessarily, wasted in unproductive work, such as law expenses, the construction of palatial termini, the reduction of lines to a dead, or nearly dead level, by embankments and cuttings, etc.; the second proposition is, that railways do not pay because they are worked on too expensive a system. If we may be allowed the expression, according to one party the statics of our railway system are to blame; according to the other the dynamics of that system are in fault. It forms no part of our purpose now to investigate questions relating to the statics of the railway system. The railways are there, with all their faults or excellencies, and cannot be altered. We must make the best of them. We propose here to consider the bearing of some of the questions connected with the dynamics of railways, that is to say, the system on which passengers and light goods are conveyed from place to place; but we wish it to be particularly understood that nothing which we may advance in favor of the use of light engines is intended to apply to the working of heavy goods or mineral trains. These can only be hauled by engines of great power; and the heaviest goods locomotives bear a comparatively reasonable proportion to the weight of the loads drawn by them—a condition favorable to economy, which has no existence in the case of passenger and other light traffic.

We are indebted to Capt. Huish's "Reports on Railway Plant," for the following statements as to the augmentation in the weight of railway rolling stock, which took place between 1831, the date at which the reports commenced, and 1848. The reports refer to what is now known as the London and North-Western system. In 1831 the average weight of the engines on the Liverpool and Manchester, and London and Birmingham Railways, was seven tons. In 1848 it was more than twice as much, being

18 tons 13 cwt. The heaviest engine in use on these lines, in the first mentioned year, was seven tons; in 1848 it was 37 tons. The weight of the carriages increased in the same period from a maximum of 3 tons 10 cwt. to 4 tons 6 cwt., and the average speed of the passenger trains had increased from 17 miles per hour to 30 miles per hour. What took place on the North-Western system accurately shows what took place through the length and breadth of the kingdom—*ex uno disce omnes*. There is not, so far as we are aware, any compendious statement in existence which will show the amount of augmentation between 1848 and 1868, but there is good reason to believe that it is very considerable. Engines weighing less than 20 tons full, are now the exception; and the average weight of all the engines working important lines in England must exceed 23 tons. The weight of carriages has also gone up, 5, 7, and even 9 tons being no uncommon weight for ordinary carriages, while on the Metropolitan Railway, carriages are used which weigh 16 tons. It does not appear that the carrying capacity of these carriages has undergone a corresponding increase. Additional strength, especially in the under frames, has been introduced, because heavy engines knock light carriages to pieces; but it does not appear that any other very valid reason for the increase of weight has been adduced, save perhaps one, viz., the modern carriages are rather more roomy and commodious than those used 20 years ago.

There is no room to doubt that the dead weight of engines was first increased in order to get more power; and had it been possible to work these heavier engines with carriages of the same weight as those employed in the earlier days of the railway system, all might have been well; twenty tons or so would have remained about the weight of the heaviest class of locomotives employed in conveying passengers; but the increased dimensions of the engines rendered a corresponding increase in the strength and weight of the vehicles drawn a necessity. The augmentation reacted on the engines, and so weight increased daily and hourly, till a new element was introduced which rendered further augmentation all but an impossibility. This new element was the stability of the permanent way. The roads could not sustain heavier loads, and therefore heavier loads were not put on them. It must not be forgotten that at one time there was a species of mania among locomotive superintendents for big engines. It was, in the first place, a very pleasant thing to be able to boast that you had bigger engines than your neighbors, just as it is a pleasant thing to have the fattest ox at a show, or the finest house in a street. In the second place, it was pleasant to know that when you stood on the foot-plate, you had beneath you a machine capable of whisking the train behind it at almost any pace you pleased. Big engines were, in a sense, luxuries, and they were paid for at a price which railway companies could not afford. Probably the first blow that the big engine craze ever received was the failure of the "Liverpool," on the London and North-Western Railway. This engine was built by Mr. Crampton, especially to compete with the large engines which Brunel, who idolized the Big, patronized on the Great Western. The "Liverpool" had 18 in. cylinders, 24 in. stroke, 2,290 ft. of heating surface, two 8 ft. driving wheels, six 4 ft. carrying wheels, an 18 ft. 6 in. wheel base, and weighed full 35 tons. The tender weighed 21 tons. Total weight, 56 tons. After working the express traffic between London and Wolverton for some time, it was found that the permanent way began to give out, and so the engine was withdrawn from active service.

After enduring for many years, the passion for large and heavy engines appears to be dying out; and engineers who not long ago regarded heavy engines as the *summum bonum* of locomotive superintendial happiness, are now quite prepared to listen to reason, to investigate patiently, and even to believe that it may be quite possible to work, if not all, still a considerable portion of the ordinary passenger traffic of our railways on a system which completely ignores heavy engines and heavy rolling stock. There is not wanting evidence that a species of revulsion of feeling is setting in, and not the least hopeful symptom is that already we hear rumors of the formation of a company, having on its board of direction some of the ablest engineers of the day, and specially called into existence to test cautiously and tentatively the merits, advantages, and disadvantages of the light rolling-stock system. What this system is we propose to tell such of our readers as are not familiar with its characteristics; and we shall further add some facts, now matters of history, which will show that the prospects of success are enormous; so enormous that we cannot account for the neglect of the system during past years on any other hypothesis than the existence of an all but universal mania for big engines, to which we have already alluded.
